**Appointments.**—The following appointments are open to all students who have passed their examinations in anatomy and physiology; (1) Casualty dresserships, (2) surgical dresserships, (3) medical clerkships, (4) pathological clerkships, (5) ophthalmic clerkships, (6) clerk to the skin department, etc. These appointments are made for three months, commencing on the first day of October, January, April, and July.

**Scholarships.**—Entrance Medical Scholarship, value about £190, open to both sexes. Six Edgar Allen Scholarships of £125 a year for three years may be held by students taking the degree course in medicine. Two Town Trustees' Scholarships, each of the value of £50, tenable for three years, for boys or girls under the age of 19 years who have been educated in a Sheffield secondary school for a period not less than two years immediately preceding the examination. Four Town Trustees' Scholarships, value £50, for boys or girls under 19 years of age, educated in any school in Sheffield, secondary or otherwise. Town Trustees' Fellowship, value £75, tenable for one year. Mechanics' Institute Fellowship, value £50 (with remission of fees), tenable for one year, and renewable for a second year. The Frederick Clifford Scholarship, value about £50, tenable for two years. Kaye Scholarship, for proficiency in anatomy and physiology, value £22 10s. Gold and bronze medals are also awarded for proficiency in various subjects.

**Fees.**—Students in the Faculty taking their complete medical course in the university pay an inclusive composition fee of £38 for each of the five years. The composition fees for the dental courses are as follows: for B.D.S., first and third years, £75; second, fourth, and fifth years, £26; for L.D.S., first and second years, £75; third and fourth years, £25. The fees for special courses taken separately can be ascertained by inquiry of the Dean.

WELSH NATIONAL SCHOOL OF MEDICINE,  
CARDIFF.

The next session opens on October 5th. The courses of instruction are open to both men and women students, and qualify for the degrees in medicine and surgery of the University of Wales, and for the degrees and diplomas of other examining bodies. Hospital instruction is given at the Cardiff Royal Infirmary, at the City Lodge Hospital, and at other recognized institutions. The Cardiff Royal Infirmary, together with its auxiliaries, has 400 beds, and is well equipped in all general and special departments, giving facilities for every branch of study. Medical practitioners wishing to prepare for the Diploma in Public Health or for the Tuberculous Diseases Diploma of the University of Wales can attend complete courses of instruction in the school. Prospectuses can be obtained on application to the Dean of the Faculty of Medicine, or to the Secretary, Welsh National School of Medicine, Newport Road, Cardiff.

## SCOTLAND.

As will be gathered from the following paragraphs, the facilities for acquiring a medical education in Scotland are very ample, whether the student be proceeding to a university degree or to a diploma. To the descriptions of the different Scottish medical centres is in some cases added an account of hospitals which either play an official part in the education given to students as yet unqualified, or offer valuable opportunities for post-graduation work.

## ABERDEEN.

THE school is conducted by the Faculty of Medicine. This comprises thirteen chairs, from which instruction is given in all the main branches of medical science—namely, botany, zoology, physics (ordinary and pre-registration), chemistry (ordinary and pre-registration), anatomy, physiology, materia medica, pathology, bacteriology, forensic medicine, surgery, medicine, and midwifery. Courses of instruction in public health and infectious diseases, tropical medicine, medical ethics, and sanatorium treatment of tuberculosis are conducted by lecturers appointed by the University Court. Special opportunities for practical instruction are afforded in the laboratories and museums attached to the departments.

Clinical instruction is obtained in the Royal Infirmary (accommodating 270 patients), the Royal Mental Hospital (900 patients), the Sick Children's Hospital (85 patients), the City Fever Hospital (250 patients), the General Dispensary, Maternity, and Vaccine Institution (10,000 out-patients annually), and the Ophthalmic Institution (3,000 patients annually). Courses of practical instruction are given in diseases of children at the Sick Children's Hospital; in fevers at the City Fever Hospital; in mental diseases at the Royal Mental Hospital; in diseases of the ear, nose, and throat at the Infirmary and Dispensary; in diseases of the eye at the Infirmary and Eye Institution; in venereal diseases and diseases of the skin at the Royal Infirmary.

The degrees granted in medicine are: Doctor of Medicine (M.D.), Master of Surgery (Ch.M.), Bachelor of Surgery and Bachelor of Medicine (M.B., Ch.B.). A Diploma in Public Health is conferred after examination on graduates in medicine of any university of the United Kingdom.

The degree of Ph.D. is also granted in this faculty.

Bursaries, scholarships, and fellowships, to the number of fifty and of the annual value of £1,180, may be held by students of medicine in this university. They range from £8 to £100 per annum, and are tenable in most cases for two or three years. The winter session begins on October 5th, 1926; the summer session on April 19th, 1927.

**Fees.**—An inclusive fee of 126 guineas is payable for instruction within the university, and the fee for the degrees of M.B., Ch.B. is 33 guineas. The total cost, including hospital fees, class and matriculation fees, and degree fees, is about £236.

## EDINBURGH.

THERE are two Schools of Medicine: the School of the University, and the School of Medicine of the Royal Colleges of Physicians and Surgeons of Edinburgh.

**THE UNIVERSITY SCHOOL.**—This school, in addition to other resources of the university, has the following means of affording practical instruction: Royal Botanic Garden, Herbarium, and Museum; Zoological Laboratory and Museum of Science and Art; Physical Laboratory; Chemical Laboratories; Dissecting Room, Bone Room, and Anatomical Museum; Physiological Laboratory; Medical Jurisprudence Laboratories; John Usher Institute of Public Health; Materia Medica Museum and Laboratory; *Post-Mortem* Department of the Royal Infirmary and University Pathological and Bacteriological Laboratory; Tutorial Classes of Practice of Physic, of Clinical Medicine, and Clinical Surgery, Surgery and Midwifery; and the practice of certain other hospitals.

**Fees.**—The essential fee for chemistry, anatomy lectures, physiology, pathology, materia medica, surgery, medicine, and midwifery is £5 5s. each. Physics, botany, zoology, forensic medicine, and

public health, £5 5s. Practical zoology, practical anatomy (summer), morbid anatomy, practical materia medica, mental diseases, practical pathology, clinical midwifery, and medical entomology and parasitology, £4 4s. Experimental physiology, diseases of tropical climates, practical botany, histology, operative surgery, clinical surgery (per term), clinical medicine (per term), and experimental pharmacology, £3 3s. Practical anatomy (winter), £6 16s. 6d. Practical chemistry, £4 14s. 6d. Regional anatomy, chemical infectious diseases of the ski-  
logy, £7 1

**Scholars** for the assistance of students by means of bursaries, scholarships, exhibitions, and money awards from the beginning to the end of their undergraduate career. In addition, there are funds which help those who have taken a first degree in medicine and surgery to continue at work as research students. The value of these awards, and the conditions attaching to them, are so varied that those interested should consult the prospectus of the school itself. No other university is in a better, even if as good a position to smooth the financial path of earnest students.

**THE SCHOOL OF MEDICINE OF THE ROYAL COLLEGES.**—This school is composed of lecturers licensed by the Royal College of Physicians and the Royal College of Surgeons, and also recognized by the university through their *licentia docendi*; for the sake of convenience they lecture in separate buildings near to the Royal Infirmary, but form a single corporate body governed by a board consisting of five members elected by the Royal College of Physicians, five members elected by the Royal College of Surgeons, and five members elected by the lecturers in the school. This board, with the assistance of the standing committees of the school, supervises the whole management and especially the maintenance of the efficiency and discipline of the school. The different buildings at present utilized for the purposes of lecturing are the following: (1) Surgeons' Hall, Nicolson Street; (2) New School, Bristo Street; (3) Nicolson Square; (4) Marshall Street; and other places. The teaching is similar to that of the Scottish universities, and the students receive similar certificates at the close of each session. The courses on the special subjects not included in the curriculum of the Examining Boards are also conducted by teachers specially qualified in each branch, and have for the last quarter of a century formed a special feature of the school. The fees payable for class and other instruction, and including the sums payable on admission to the examination of the Conjoint Board for the triple qualification, amount to about £180. The Calendar, giving full information regarding classes and fees, can be obtained (price 6d.) on application to the Dean of the School, 11, Bristo Place, Edinburgh.

**WOMEN STUDENTS IN EDINBURGH.**—Until the close of the summer session of 1916 women students intending to proceed to graduation in the University of Edinburgh, as well as those entering for the triple qualification of the Royal Colleges of Edinburgh and Glasgow, received their training in the Edinburgh School of Medicine for Women. Now women students study under the same conditions as men, and may obtain either the university degree or the diploma of the Royal Colleges. In the university systematic lectures are given to them by the professors in the ordinary classes, which are therefore mixed. In clinical medicine and clinical surgery, however, while the lectures are attended by mixed classes, the women students are restricted to the wards of one charge. The particular wards are changed every term, each of the physicians and surgeons to the infirmary taking the women students in rotation. With few exceptions, prizes, scholarships, bursaries, and similar distinctions are open to women under the same conditions as for men. The women students also have the same privileges as in the past have been given to the men of attending a certain proportion of the extra-mural classes taught by the lecturers of the School of Medicine of the Royal Colleges. Most of the Students' Societies are open to women, with the exception of the University Union and the Royal Medical Society. Their place is taken by the Women Students' Union and the Women's Medical Society. There is also a Women's Athletic Club, with playing fields gifted to it by the university. Information on matters connected with women's studies may be obtained from the Lady Warden, University New Buildings, Edinburgh.

## MEDICAL SCHOOLS IN SCOTLAND.

**GLASGOW.**—The whole course of study required for graduation (M.B., Ch.B.) at the University of Glasgow can be taken here. Besides ample provision for lectures there is practical and clinical work at the hospitals, and practical courses are conducted in the Pathology, Public Health, Pharmacology, Physiology, laboratories of the following departments: Surgery; Anatomy, Chemistry, Zoology, Physics, and Botany; the Botanic Garden and the Hunterian Museum (Pathology) are also open to students. New buildings and equipments have been provided for botany, zoology, for practical anatomy, for operative surgery, as well as for pathology; the very large additions made a number of years ago to the chemical laboratory rendered it one of the most extensive in Scotland. The classrooms and laboratories for the departments of Physics, Physiology, Pharmacology, Materia Medica, Medical Jurisprudence, and Public Health are also of recent erection, and are elaborately equipped. Four additional chairs of Medicine, Surgery, Obstetrics, and Pathology have been recently established, the professors being specially attached to the Royal Infirmary; and a number of university lectureships in Clinical Medicine, Clinical Surgery, Venereal Diseases, Laryngology, Dermatology, Otology, Psychological Medicine, Tuberculosis, and Electrical Diagnosis and Treatment have been founded at the university. Five other chairs have been founded at the university, in Bacteriology, Organic Chemistry, Physiological Chemistry, Applied Physics, Public Health, and another in Pediatrics. There are also lectureships on Electrical and Medical Therapeutics. The university, in short, has made great and successful efforts to extend and improve the accommodation of the medical departments, to strengthen the teaching staff, and to encourage post-graduation and research work. A Diploma in Public Health is now also granted. Three very extensive general hospitals in the city afford exceptional opportunities for clinical instruction—namely, the Western Infirmary (600 beds), near the university, to which the Regius Professors are attached; the Royal Infirmary (688 beds); and the Victoria Infirmary (260 beds); while the Royal Hospital for Hospital, Gartnavel (460 beds), the Royal Maternity and Sick Children (275 beds), the Glasgow Eye Infirmary (100 beds), the Ophthalmic Institution (35 beds), the fever hospitals at Belvidere (680 beds) and Ruchill (540 beds), and other institutions afford facilities for the practical study of special branches. The large general hospitals of the parish council are now also available for clinical instruction in medicine and surgery. Information regarding post-graduate study will be found at page 449.

**Bursaries.**—Bursaries confined to the Medical Faculty amount in annual value to about £1,000, while bursaries in any faculty, amounting to about the same annual sum, may be held by students of medicine, a number of both sets being open to women. Several valuable scholarships may be held by medical students who have graduated in arts.

The following bursaries are open to undergraduates of both sexes. The Gibson Bursary, annual value £36, tenable for four years. This is open to medical students who are preparing for service as medical missionaries in connexion with the Church of Scotland, and will be awarded to the eligible candidate who has gained the highest number of marks in the First Professional Examination. The Arbroath Bursary, annual value £40, tenable for three years, is awarded by the Senate, on the recommendation of the Faculty of Medicine, to the student who is of the highest merit among the candidates, as shown by their class records and their performances in the First and Second Professional Examinations. One Logan Bursary, annual value £16, tenable for four years; appointment by the Senate. Six Lorimer Bursaries (each £20 and tenable for one year) are awarded to the best students in each of the following classes: botany, zoology, physics, chemistry, anatomy, physiology. The Macintosh Mental Science Bursary in medicine, of the value of £31, is awarded annually to the student (of either sex) attending the class of insanity who stands first in an examination in that subject, the bursar to continue the practical study of the subject to the satisfaction of the Faculty of Medicine. The Gardiner Bursary, annual value £14, tenable for two years, will be awarded after the autumn professional examination to the candidate who has passed in physiology at the Second Professional Examination, and whose aggregate of marks in that subject and in chemistry and physics of the First Professional Examination is the highest. Of the eight James A. Paterson Bursaries two are awarded each year; they are of the value of £30 and £20 respectively, and are tenable for four years;

examination in mathematics and natural philosophy in June for students entering the first and second years of medical study. The following are tenable in any faculty: Four Nivison Bursaries (each £20 and tenable for four years), two Pratt Bursaries (each £20 and tenable for four years), and two Taylor Bethia Stewart Bursaries (£50 each, tenable for three years); candidates must have taken the M.A. degree of Glasgow. There is a special examination. Nine Glasgow Highland Society's Bursaries, for students of Highland descent, of the annual value of £25, and tenable for five years; two vacant each year.

The Carnegie Trust for the Universities of Scotland is empowered to pay the whole or part of the university ordinary class fees of students of Scottish birth or extraction, under conditions given in the *University Calendar*, and summarized at page 428 of this issue. The Dobbie Smith Gold Medal is awarded for the best essay on a prescribed subject within the science of botany. The Brunton Memorial Prize of £20 is awarded annually to the most distinguished graduate in medicine of the year, and the West of Scotland R.A.M.C. Memorial Prize to the candidate for the degrees of M.B., Ch.B., who obtains the highest aggregate marks in medicine, surgery, and midwifery in the Final Examinations. The University Commissioners have issued an ordinance to make regulations for the admission of women to certain bursaries, scholarships, and fellowships. Scholarships and fellowships are offered by the Carnegie Trust in science and medicine for post-graduation study. There are also four McCunn Medical Research Scholarships (two of £200 and two of £400) for graduates in medicine of the Scottish universities; one Faulds Fellowship for Research in Medical Science of approximately £200 for one year; and one Strang Steel Scholarship value £160 for one year. There is, in addition, "The Captain H. S. Rankin, V.C., Memorial Prize" in Pathology.

**Fees.**—The matriculation fee for each year is £2 2s. In most cases the fee for each university class is £6 6s., but in some cases it is £4 4s. For hospital attendance at the Western Infirmary students pay £12 12s. for a perpetual ticket, or £1 11s. 6d. for a single term ticket, with an additional fee of £5 5s. for each winter and £2 12s. 6d. for each summer clinical course. The fees for the four professional examinations total £34 13s. For the whole curriculum the fees for matriculation, class attendance, hospital attendance, and professional examinations amount to about £250. For further information apply to the Registrar, Glasgow University.

**QUEEN MARGARET COLLEGE.**—In this, the Women's Medical School of the University of Glasgow, the courses of study, degrees, regulations, fees, etc., are the same as for men. Women students have their own buildings, with classrooms, reading rooms, library, etc. They are taught in some classes apart from male students, in others together with them, but in either case have all the rights and privileges of university students. Their clinical studies are taken in the Royal Infirmary, where wards containing 520 beds are available for their use, and in its dispensary; and similarly in the Western Infirmary and in the Victoria Infirmary; also in the Royal Hospital for Sick Children, the Glasgow Ear Hospital, the Royal Asylum, Gartnavel, Hawkhead Asylum, the Ophthalmic Institution, the City of Glasgow Fever Hospitals, Belvidere and Ruchill, and the Glasgow Royal Maternity and Women's Hospital.

**Scholarships.**—The Arthur Scholarship, annual value £20, tenable for three years. Open to competition by medical students of first year at the First Professional Examination in October, 1928. This scholarship is restricted to women medical students. Full information can be obtained from the Mistress, Queen Margaret College, Glasgow.

**Board for Students.**—University houses of residence for women students, Queen Margaret Hall and Robertson Hall, are situated near the College. The cost of board and residence is from 32s. 6d. to 42s. a week, according to accommodation. Applications to be made to the Wardens. Another hostel near the College is South Park House, Ann Street, belonging to the Student Christian Movement, and open to women students of all colleges in Glasgow. Cost of board is from 28s. to 30s. weekly. Applications to be made to the Warden.

**ST. MUNGO'S COLLEGE.**—This is the Medical School of the Royal Infirmary, which is the largest general hospital in Glasgow. The infirmary is situated in Cathedral Square, Castle Street, and has car communication with every part of the city. St. Mungo's College is in the subjects of the grounds, and affords full courses in all the subjects of the medical curriculum, and in all the medical subjects of the dental curriculum.

The infirmary has (including the ophthalmic department) over 700 beds, the average number occupied in 1924 being over 725. There are special beds and wards for diseases of

women, of the throat, nose, and ear, venereal diseases, burns, and septic cases. In the out-patient department in 1925 over 51,000 patients were treated. In addition to the large medical and surgical departments, there are departments for special diseases—namely, diseases of women, of the throat and nose, of the ear, of the eye, of the skin, and of the teeth. There is also a fully equipped electrical pavilion, with the latest and most improved apparatus for diagnosis and treatment.

**Appointments.**—Five house-physicians and eleven house-surgeons, who must be fully qualified, are appointed every six months, and board in the hospital free of charge. Clerks and dressers are appointed by the physicians and surgeons. As many cases of acute diseases and accidents of a varied character are received, these appointments are very valuable.

**Fees.**—The average class fee is £3 3s. for summer classes and £4 4s. for winter classes. The fees for all the lectures, practical classes, and hospital attendance necessary for candidates for the diplomas of the English or Scottish Colleges of Physicians and Surgeons amount to about £120. The classes are open to male and female students.

A syllabus of classes can be obtained on application to the Secretary to the Medical Faculty, St. Mungo's College, 86, Castle Street.

**THE ANDERSON COLLEGE OF MEDICINE.**—This school provides education in all subjects of the curriculum for both medical and dental students. The school buildings are situated in Dumbarton Road, immediately to the west of the University and Western Infirmary. The hospital practice and clinical lectures are provided in the Western or Royal Infirmary; pathology in the Western or Royal Infirmary; vaccination and dispensary practice in the Western or Royal Infirmary Dispensary. These classes are recognized by all the licensing corporations in the United Kingdom, also by the Universities of London, Durham, Glasgow, and Edinburgh (the latter two under certain conditions stated in the school Calendar). The courses (lectures and laboratory) in public health are recognized by the Scottish Licensing Board, the Universities of Oxford, Cambridge, and London, and the London and Irish Colleges.

**Fees.**—The fees for the lectures and practical work required by ordinary students range between 2 and 5 guineas a session. In the Public Health Department the fee for a six months' course is £14 14s. The Carnegie Trust pays the fees of students at Anderson College on conditions regarding which particulars may be obtained from the Secretary, Carnegie Trust Offices, Edinburgh.

A Calendar will be sent on receipt of a postcard by the Secretary to the Medical Faculty, the Anderson College of Medicine, Glasgow, W., who will forward any further information which may be desired.

The Royal Samaritan Hospital for Women, Glasgow, with over 90 beds, offers facilities for clinical instruction in the diseases peculiar to women.<sup>1</sup> Particulars may be obtained from Mr. T. Mason Macquaker, M.A., secretary, 149, St. Vincent Street, Glasgow.

#### ST. ANDREWS AND DUNDEE.

**THE** medical departments in these two teaching centres cater specially for students proceeding to the degrees of the University of St. Andrews, but admit other students as well. In the former city the United College provides education in all subjects for the first two years. In Dundee, University College provides for the needs of students from the beginning to the end of the five years' curriculum. Its buildings are modern, and contain fully equipped laboratories. The clinical work of the school is facilitated by various institutions. The class fees are from £6 6s. to £5 12s. 6d. for systematic classes, and from £4 14s. 6d. to £4 4s. for practical classes. The hospital ticket is £1 8s. for three months, £4 4s. a year, or perpetual, £13 6s. 8d. in one sum. The inclusive or composition fee for the curriculum is £182. In connexion with both institutions there are bursaries and scholarships of considerable value, which are awarded after competitive examination. Information as to these can be obtained from the Secretary of the University of St. Andrews. Information regarding the clinical facilities may be obtained from the Dean of the Medical Faculty, Medical School, Dundee.

<sup>1</sup> University Lectureship associated with the Hospital, the Royal Samaritan Lectureship in Gynaecology. Lecturer: David Shannon, M.B., Ch.B., L.M., T.D.

#### Clinical Work.

Good opportunities for clinical work are afforded by the Dundee Royal Infirmary, the instruction given thereat being recognized for purpose of the Scottish universities, the University of London, the University of Edinburgh, and by the Royal Colleges of England and Scotland.

#### IRELAND.

THERE is a choice of six schools for those pursuing their medical studies in Ireland. For clinical instruction the choice is equally satisfactory and varied, though the hospitals themselves are comparatively small. Some account of the schools follows.

#### DUBLIN.

##### School of Physic.

THIS school is in Trinity College, Dublin, and is carried on under the joint auspices of the University of Dublin and of the Royal College of Physicians of Ireland, the King's professors of institutes of medicine (physiology), practice of medicine, materia medica, and midwifery being appointed by the latter. Clinical instruction is given at Sir Patrick Dun's Hospital, and some twelve other metropolitan hospitals and asylums are recognized by the Board of Trinity College. The courses of instruction are open to all medical students, whether they belong to the university or not.

##### The Schools of Surgery.

These are schools carried on in Dublin under the supervision and control of the Council of the Royal College of Surgeons. They are formed of the College's own school, combined with two famous old medical schools—Carmichael and Ledwich; they are attached to the College by charter. The buildings contain spacious dissecting rooms, special pathological, bacteriological, public health, chemical, and pharmaceutical laboratories. Advantage can be taken of the lectures and instruction afforded by students otherwise unconnected with the College.

**Prizes.**—Among the prizes annually awarded are: The Birket Anatomical Prize (£26 5s.); the Carmichael Scholarship (£15); the Mayne Scholarship (£8); the Gold Medal in Surgery, the Stoney Memorial Gold Medal in Anatomy, the H. Macnaughton Jones Gold Medal for Midwifery and Gynaecology; class prizes, accompanied by silver medals, will also be given in each subject.

A prospectus can be obtained post free on application to the Registrar, Royal College of Surgeons, Dublin.

##### University College, Dublin.

This is one of the constituent colleges of the National University of Ireland. The arrangements for the teaching of medical students from beginning to end of the curriculum are adequate. Applications for other information may be addressed to the Secretary and Bursar, University College, Dublin.

##### Clinical Work.

There are numerous well arranged hospitals in and around the city, and almost all of these are recognized for teaching purposes by the Conjoint Board of Ireland, the University of Dublin, the National University of Ireland, and by like bodies elsewhere in the British Isles. Among them are the Mater Misericordiae Hospital, with 345 beds; Dr. Steevens's Hospital at Kingsbridge, with 150; Meath Hospital and County Dublin Infirmary, with 160; Mercer's Hospital, close to Trinity College, with 120; the Royal City of Dublin Hospital, with 124; the Adelaide Hospital, with 140; the Royal Victoria Eye and Ear Hospital, with 100 beds; Sir Patrick Dun's, which has a direct connexion with the School of Physic, and the combined institutions formed by the Hardwicke Fever Hospital, the Richmond Surgical Hospital, and the Whitworth Medical Hospital, with an aggregate of 250 beds.

As for the famous Dublin medical institution known as the Rotunda Hospital, this practically consists of two distinct hospitals, and is believed to be the largest combined maternity and gynaecological hospital in the British Isles. It receives nearly 3,000 patients every year, and,

SEPT. 4, 1926]

## CLINICAL HOSPITALS IN ENGLAND.

apart from ordinary out-patient work of a gynaecological order, annually attends some 2,000 women at their own homes during their confinement. It possesses residential quarters for students, and, taken as a whole, offers exceptional opportunities for study both to ordinary students and to medical graduates of any nationality.

## BELFAST.

The Medical School is part of the Faculty of Medicine of Queen's University, Belfast, and provides a complete medical curriculum for all purposes. The laboratories in connexion with the departments of biology, chemistry, physiology, pathology, anatomy, physics, and materia medica are all excellent, and there is a Students' Union which gives students the advantages of dining rooms, reading rooms, a library, and various recreation rooms. Women are eligible as students. Clinical instruction is given at the Royal Victoria Hospital, which was rebuilt a few years ago and has 300 beds, and the Mater Infirmorum Hospital, which has 150 beds. Other hospitals open to the students of the university are: the Maternity Hospital, the Ulster Hospital for Women and Children, the Benn Ulster Eye, Children, the Ophthalmic Hospital; the Benn Ulster Hospital for Ear and Throat; the Union Infirmary and Fever Hospital; the Fever Hospital, Purdysburn; the District Lunatic Asylum, the Samaritan Hospital, Forster Green Hospital for Diseases of the Chest, and the Belfast Hospital for Skin Diseases.

**Scholarships.**—(1) Twelve, of the value of £40 each, are assigned as Entrance Scholarships in the Faculties of Arts, Science, and Medicine, tenable for one year; (2) sixteen Professional Scholarships, value from £15 to £40 each; (3) one Hutchinson Stewart Scholarship, £12, in mental diseases; (4) one Mackay Wilson Travelling Scholarship, £100, awarded triennially; (5) Isabella Tod Memorial Scholarship, tenable for three years, awarded triennially to a woman student; (6) Magrath Clinical Scholarship, awarded annually, value about £112; (7) two Musgrave Studentships of £200 in Physiology and Pathology. There is also a post-graduate research fund, open to all graduates of not more than three years standing. Gold medals are awarded at the M.D. examination.

**Fees.**—The cost of the curriculum intended for students proceeding to the degrees of the Queen's University of Belfast is, approximately, £200. This includes examination fees and a perpetual ticket for attendance at the Royal Victoria Hospital or the Mater Infirmorum Hospital, and fees for the special hospitals. The course for the Conjoint Board costs about the same amount.

The Regulations of the Medical Faculty, containing full information, can be obtained on application to the Secretary, Queen's University, Belfast, price 4d.

## UNIVERSITY COLLEGE, CORK.

This institution, formerly known as Queen's College, Cork, is one of the constituent colleges of the National University. It holds examinations for all the faculties of that university. In addition to continuing the work which it has hitherto performed—namely, that of providing education adapted to the needs of medical students at all stages of their career—its first aim is to fit students for the degrees of the National University, but students proceeding for the examinations of the Conjoint Board of England, Scotland, or Ireland, the Society of Apothecaries of London, or the Apothecaries' Hall of Ireland, or London University, can arrange the courses of lectures which they attend, and the order in which they attend them, to meet the requirements of those bodies. Certificates of attendance at the college courses are also accepted by the University of South Ireland. Clinical instruction is given at the Cork Union Hospital (each 100 beds) and at the Mercy Hospital, (1,200 beds). Students can also attend the Mercy Hospital, the County and City of Cork Lying-in Hospital, (130 beds), the County and City of Cork Lying-in Hospital, the Maternity, the Hospital for Diseases of Women and Children, the Fever Hospital, the Ophthalmic and Aural Hospital, and the Eglinton Lunatic Asylum. The session extends from October to June.

There is a Dental School in which the degree of Bachelor of Dental Surgery of the National University of Ireland can be obtained. There is a large well equipped dental hospital in connexion with the school.

**Scholarships.**—Over £4,000 is available annually for scholarships in the College. Particulars as to each of them can be obtained on application to the Registrar.

**Fees.**—The fees for the lectures and hospital attendances required by the National University of Ireland course, including examination fees, come to about £150. Further information can be found in the Calendar or obtained on application to the Registrar.

## UNIVERSITY COLLEGE, GALWAY.

This institution is one of the constituent colleges of the National University of Ireland, and includes Faculties of Art, Science, Law, Celtic, Engineering, Commerce, and Medicine. The college buildings are well lighted and well ventilated, and contain dissecting rooms, an anatomical theatre, and laboratories for the study of physiology, chemistry, physics, and other departments of medical science. For pathology and chemistry new laboratories are now provided. It has good grounds surrounding it, and there are many arrangements, such as a library, a college union, and an athletic union, for the benefit of students in other departments of the college. The clinical teaching, which is recognized as qualifying not only for the degrees of the National University, but for those of London University and the diplomas of the various colleges in the three kingdoms, is carried on at the Galway Central Hospital and the Galway Tuberculosis Hospital. The Galway Central Hospital is a general hospital, and at the two hospitals students have ample opportunities of studying zymotic and chronic diseases. The Central Hospital has a special ward for diseases of children. Each year the governing body offers about £1,500, and the County Councils of Connaught offer about £3,500, in scholarships. These scholarships are tenable in any faculty. Additional information regarding these scholarships can be obtained on application to the Registrar, and to the Secretaries of the Connaught County Councils.

## CLINICAL HOSPITALS IN ENGLAND.

Many hospitals in Great Britain and Ireland, though not connected with any medical school, open their doors either to those who have yet to be qualified, to those who are doing post-graduation work, or to both. The facilities they offer for gaining practical clinical experience are very great, and should not be overlooked. Their honorary staffs commonly make a point of giving such instruction as opportunity offers, and at those situated in the larger towns there are often appointments as clinical assistants to be obtained. In addition, they all have to offer, at shorter or longer intervals, appointments for resident medical officers, house-physicians, and house-surgeons. These are usually paid offices, which may be held for periods varying from six months to a year. Some of those situated in the great medical centres in the provinces, and in Scotland and Ireland, have already been mentioned in speaking of the medical schools in these localities; but it should be added that there are many other provincial hospitals where admirable work is done, and at which much valuable experience can be gained by both senior and junior students, and by those already qualified. Cases in point are the Royal Infirmary, Bradford; the Royal Sussex County Hospital, Brighton; the Royal United Hospital, Bath; the Kent and Canterbury Hospital; the Derbyshire Royal Infirmary; the South Devon and East Cornwall Hospital, Devonport; the Royal Albert Hospital and Eye Infirmary, Devonport; the Royal Devon and Exeter Hospital; the West of England Eye Infirmary, Exeter; the Gloucestershire Royal Infirmary and Infirmary, Exeter; the Royal Infirmary, Northampton; the Eye Institution; the General Hospital, Northampton; the Hospital, Lincoln; the General Hospital, the Royal Norfolk and Norwich Hospital; the General Hospital, the Royal Nottingham; the Royal Portsmouth Hospital; the Royal Berks Hospital, Reading; the Royal South Hants and Southampton Hospital; the Staffordshire General Infirmary, Stafford; the North Staffordshire Infirmary at Hartshill; the Royal Hants County Hospital, Winchester; the County Hospital, York; and the Coventry and Warwickshire Hospital.

*London Clinical Hospitals.*

'As for the hospitals in the metropolis, so many of these take a share in the giving of clinical instruction that it is worth while to classify them.

*Children's Hospitals.*—There are at least seven of these, the leader among them being the Hospital for Sick Children, Great Ormond Street, which has 240 beds. There are also the East London Hospital for Children, Shadwell, with 124 cots; the Queen's Hospital for Children, Bethnal Green, with 134; the Victoria Hospital for Children, Chelsea, with 104; the Belgrave Hospital for Children, which has a considerable out-patient department, but in-patient accommodation for only 40 children; the Paddington Green Children's Hospital, an institution of about the same size; and the Evelina Hospital for Sick Children, Southwark Bridge Road, with 76 beds. The largest and the oldest of the hospitals for both women and children is the Royal Waterloo Hospital for Children and Women, Waterloo Road, S.E.1.

*Hospitals for Women.*—Queen Charlotte's Maternity Hospital, Marylebone Road, with 70 beds and a residential college for and practitioners, specializes in the teaching of midwife. Samaritan Hospital for Women, Marylebone Road, admits qualified practitioners as clinical assistants to both the in-patient and out-patient departments; demonstrations are given daily in both departments, the fees—payable in advance—being £3 3s. for three months; full particulars may be obtained from the secretary. In addition may be mentioned the Hospital for Women, Soho Square, whose teaching is confined to post-graduates in limited numbers; the Chelsea Hospital for Women, Arthur Street, Chelsea; and the Elizabeth Garrett Anderson Hospital for Women in Euston Road, the latter being in the nature of a general hospital so far as concerns the class of case treated.

*Eye Hospitals.*—The largest of these is the Royal London Ophthalmic Hospital (Moorfields), City Road. At this hospital two complete courses of instruction are given during the year—October to February and March to July—comprising the following subjects: anatomy, physiology, and optics; ophthalmic medicine and surgery—(1) external diseases, (2) motor anomalies and squint, (3) ophthalmoscopic conditions (weekly classes), (4) pathology; practical refraction classes; methods of examination (practical); operative surgery; practical pathology; practical bacteriology; x-ray and radiotherapy; clinical lectures; discussion classes. A fee of 24 guineas entitles the holder to one full five months' course (with the exception of practical pathology and practical bacteriology), together with a permanent ticket for the practice of the hospital. Fee for the practice of the hospital (permanent), £5 5s.; for three or six months, £3 3s.; for two months, £2 2s.; for one month, £1 1s. Gentlemen are eligible, under certain conditions, for the posts of chief clinical assistant, clinical assistant, and junior assistant. Clinical work takes place every morning at 9 o'clock, and operations at 10. An additional special course in the preliminary subjects (namely, anatomy, physiology, and optics) for the D.O.M.S. and other examinations in ophthalmology will be held immediately preceding the date of the examination. The fees for this course will be 12 guineas, or £5 5s. for any subject separately. Further particulars may be obtained from the Dean of the Medical School. Other eye hospitals are the Royal Westminster Ophthalmic Hospital near Charing Cross, the Royal Eye Hospital, Southwark, and the Central London Ophthalmic Hospital, Judd Street, W.C.1, each with about 40 beds.

*Fever Hospitals.*—The Metropolitan Asylums Board has under its control a good many institutions in and around London for the treatment of the more serious zymotic disorders; it makes special arrangements for the instruction of students in this subject, and grants certificates at the end of the courses. Detailed information should be sought from the Clerk to the Board, Victoria Embankment, E.C.4.

*Chest Hospitals.*—The largest of these is the Brompton Hospital for Consumption, which has 333 beds and a large sanatorium at Fimley with 150 beds. There is also the City of London Hospital for Diseases of the Chest, Victoria Park, with 175 beds, and the Royal Hospital for Diseases of the Chest, City Road, now amalgamated with the Royal Northern Hospital, Holloway Road.

*Nose, Throat, and Ear Hospitals.*—The institutions which confine their work to disorders of the throat, nose, and ear all make special arrangements for the benefit of senior and post-graduate students. They are the Metropolitan Ear, Nose, and Throat Hospital, Finsbury Square; the Royal Ear Hospital, Dean Street; the Central London Throat, Nose, and Ear Hospital, Gray's Inn Road; and the Hospital for Diseases of the Throat, Golden Square—the last, which possesses 75 beds, being the largest of the four institutions.

*Miscellaneous Special Hospitals.*—Among these are the Bethlem Royal Hospital, St. George's Fields, S.E.1, which (like the Maudsley Hospital) confines its work to the treatment of mental diseases, and includes a department for nervous and early mental disorders. West End Hospital for Nervous Diseases, 73, Welbeck Street, W.1. St. Peter's Hospital for Stone and Urinary Diseases, 11, Arnetta Street, Covent Garden. St. Mark's Hospital, City Road, which devotes itself to the treatment of diseases of the rectum, including cancer and fistula. The National Hospital for Diseases of the Heart in Westminster Street, W.1. St. John's Hospital for Diseases of the Skin in Leicester Square; the Hospital for Diseases

of the Skin, Stamford Street, Blackfriars; and the National Hospital, Queen Square, W.C.1, an institution possessing 200 beds and a world-wide reputation.

Detailed information as to the teaching arrangements of all these institutions may be obtained on application to their secretaries.

**WOMEN IN MEDICINE.**

THE regulations of the General Medical Council and of the various universities and colleges set out in previous sections apply to women as to men.

*Examinations.*

Women are admitted to all the medical examinations of the following qualifying bodies: the Royal College of Physicians; the Royal College of Surgeons of England; the Society of Apothecaries of London; the Conjoint Boards in Scotland and in Ireland; and all the universities of Great Britain and Ireland. The Royal College of Physicians now allows women to be eligible for election as Fellows.

*Medical Education.*

The London (Royal Free Hospital) School of Medicine for Women, which is one of the constituent schools of the Medical Faculty of the University of London, is the sole school for medical education which admits women only. All the resident appointments at the Royal Free Hospital, of which there are nineteen yearly, are held by women. Arrangements are made for students of the school to obtain clinical instruction at the Hospital for Sick Children, Great Ormond Street; the National Hospital for Nervous Diseases; the Royal London Ophthalmic Hospital (Moorfields); the Elizabeth Garrett Anderson Hospital; the South London Hospital for Women; and the Cancer Hospital. Further particulars with regard to the London School of Medicine for Women will be found on page 437.

Women are also admitted to the following men's schools in London: University College Hospital (a limited number only); King's College Hospital; Charing Cross Hospital; and the Westminster Hospital. Further particulars about these schools will be found in the article on London Medical Schools at page 432 et seq. The medical schools of Birmingham, Bristol, Cardiff, Leeds, Liverpool, Manchester, Newcastle, and Sheffield admit women. In Scotland, the medical schools of Aberdeen, St. Andrews, Edinburgh, and Glasgow admit women, although they do not in every case afford them equal facilities with men. The Irish universities and colleges are open to women.

*Openings for Medical Women.*

The London School of Medicine for Women celebrated its jubilee in October, 1924. During the fifty years of its existence over 1,000 women have graduated from this school. At the present time most of them are engaged in active medical work. Unemployment is apparent in all professions, and applies to both sexes; it is asserted that medical women are rather more fortunate in this respect than women in other professions. In private practice they do increasingly well, and are reported to be in great demand as locumtenents for medical men and women.

The Public Health Service, and especially its department of Maternity and Child Welfare, provides openings for women. In addition nearly all the voluntary welfare centres in the country are officered by medical women. The rapid growth in recent years of maternity and child welfare centres has given women, to whom such work is peculiarly suited, an opportunity of participating in this important branch of preventive medicine. Under the Board of Education there are appointments for women as medical advisers and school medical inspectors. The London County Council has medical women as lecturers and examiners on the care of children, home nursing, health, and first aid. Many of the venereal disease clinics have at least one medical woman on the staff. A certain number of appointments as tuberculosis officer are held by women. Appointments are held by women as residents in general hospitals, hospitals for women and children, sanatoriums, infirmaries, fever hospitals, and asylums.

Particulars of the Colonial appointments which may be held by women in British West Africa and the Malay States can be obtained from the Medical Branch of the Colonial Office. Information regarding the women's medical service for India may be obtained from the honorary secretary, United Kingdom Branch of the Countess of Dufferin's Fund, c/o General J. B. Smith, India Office, Whitehall, S.W.1. Missionary societies also offer employment to medical women. Further particulars can, we understand, be obtained from Dr. Webb Anderson, Medical Missionary Association, 49, Highbury Park, London, N.5.

#### *Equal Pay for Equal Work.*

The British Medical Association was the first of all professional organizations to lay down the principle that no distinction should be made on the ground of sex as regards the emoluments to women members of the profession. Attempts are continually being made by public authorities to obtain the services of women doctors at lower salaries than those paid to men, and the Association looks to all medical women to help it in resisting such attacks upon the solidarity of the profession. In its constant efforts to maintain this principle the Association works in close co-operation with the Medical Women's Federation (9, Clifford Street, New Bond Street, W.1). In defence of the principle the British Medical Association has at various times fought—usually with success—Government departments and local authorities of all kinds. Where the authorities concerned have declined to recognize the justice of the claim that equal pay should be given for equal work the machinery, local and central, of the Association has been put into operation, and as a result the authority has generally seen fit to drop the proposed distinction between men and women practitioners or given up the attempt to fill the post. It is hardly necessary to add that the British Medical Association can only be successful in carrying out this policy if it receives the loyal support of all medical women.

### DEGREES FOR PRACTITIONERS.

At one time it was almost the universal custom for medical students educated in London and aiming at general practice not to seek a university degree, and as that custom still prevails to a considerable extent a large proportion of medical men in England possess diplomas or licences to practise but not degrees in medicine. This is a fact which they sometimes find reason to regret, and to such practitioners the following paragraphs may be of interest. It should be noted, however, that the M.D.Brux. diploma, if obtained subsequently to June, 1886, is not registrable, and that the University of Brussels no longer holds special examinations for foreign medical practitioners.

#### UNIVERSITY OF DURHAM.

The degree of M.D. is granted by the University of Durham to registered practitioners of not less than fifteen years' standing, who have been qualified and in practice for that period, upon the following conditions, without residence: The candidate must be 40 years of age, and must produce a certificate of moral character from three registered medical practitioners. Should he not have passed an examination in arts previous to the professional examination in virtue of which his name was placed on the *Register*, he is examined in classics and mathematics; if otherwise, he is required to translate into English passages from any one of the following Latin authors: Caesar, *De Bello Gallico* (first three books), Virgil *Aeneid* (first three books), or Celsus (first three books). Natives of India or the British Colonies are placed on the same footing as natives of Great Britain. Natives of India must produce evidence from an Indian university that they have passed within one year an examination in Latin.

*Professional Examination.*—The candidate must pass an examination in the following subjects: (i) Principles and practice of medicine, including psychological medicine, hygiene, and therapeutics; (ii) principles and practice of surgery; (iii) midwifery and diseases of women and children; (iv) pathology, medical and surgical; (v) anatomy, medical and surgical; (vi) medical jurisprudence and

toxicology. Candidates are examined by means of written papers, clinically, and viva voce, at the College of Medicine, Northumberland Road, Newcastle, and in the Royal Victoria Infirmary. The classical part of the examination may be taken separately from the professional on payment of a portion (£10 10s.) of the full fee.

The examinations are held twice a year, towards the end of June and of December. Notice, accompanied by the fee and certificates, must be sent to Professor Howden, Registrar of the University of Durham College of Medicine, Newcastle-on-Tyne, at least twenty-eight days before the commencement of the examination.

*Fees.*—The fee is 50 guineas, which includes the degree fee; if a candidate fail to pass, 20 guineas are retained, but if he present himself again 40 guineas only are required.

#### UNIVERSITY OF BRUSSELS.

Although the University of Brussels has discontinued the holding of special examinations for foreign medical practitioners desirous of obtaining the M.D.Brux. diploma, it is possible for a foreigner who is willing to undergo the prescribed courses and tests to obtain in Brussels a diploma of "Docteur en médecine, chirurgie et accouchements," which, though it does not entitle to practise in Belgium, is of the same standard as the Belgian legal diploma. All candidates are required to submit their degrees or diplomas for consideration to the secretary of the university, and must be prepared to spend a period at the university attending the lectures, clinics, and practical work, before being allowed to enter for the examinations, which are conducted in French, viva voce. Ophthalmology is now a compulsory subject. The period of residence required will vary according to the standard of the degree or diploma submitted by the candidate for the consideration of the university authorities, and may be one, two, or three years. October is the best month for commencing. The fees for each year are: Courses, 525 francs; laboratory work, 250 francs; examinations, 110 francs. We understand that Dr. A. D. Woolf, of 13, The Avenue, Higham's Park, E.4, Honorary Secretary of the Brussels University Medical Graduate's Association, will, on application, give further particulars with regard to the preparation for the degree.

### POST-GRADUATION STUDY.

THE chief step forward in the development of a scheme for post-graduate medical study in London during the past year was the inauguration of a social centre or hostel for post-graduates at the Imperial Hotel, Russell Square. We commented on this in the *BRITISH MEDICAL JOURNAL* of July 10th (p. 82). The hostel should be of great value in helping to form a body of post-graduate opinion. The committee appointed last year by the Minister of Health to draw up "a practical scheme of post-graduate medical education centred in London" has not yet reported, so that it is still impossible to say whether Great Britain is likely to take her place with Vienna and Berlin in offering international post-graduate courses to students from all parts of the world. There is no doubt that the aim should be to establish in London a real organization, possibly linked up with schools in the provinces, capable of offering provision for study which will attract men of capacity from the Dominions, America, and foreign countries, and at the same time offering courses which will benefit practitioners in this country. For the latter part of this programme facilities already exist, both in London and the provinces; and in many cases progress can be reported. The Fellowship of Medicine, founded in 1918, and amalgamated with the Post-Graduate Medical Association in 1919, continues to function from the office generously placed at its disposal by the Royal Society of Medicine (1, Wimpole Street, W.1). Courses of instruction at various hospitals scattered through London are organized, and a list of hospitals which welcome post-graduates, together with the names of the teachers, is kept. Permanent schools for those who desire to revise or increase their medical knowledge exist in the West London Post-Graduate College and the North-East London Post-Graduate

College. Some of the large undergraduate teaching hospitals provide short post-graduate courses, and at St. Bartholomew's Hospital a special vacation course for a fortnight in September is now a regular institution. In the provinces the Universities of Oxford, Birmingham, Bristol, Manchester, and, this year, Sheffield, have organized courses. At Manchester it is hoped to start a central scheme of training, taking the form, perhaps, of a definite post-graduate school. In Scotland considerable progress has been made. Edinburgh receives graduates from many schools in the Dominions, as well as in this country. At Glasgow teaching is provided under three schemes: a general course of four weeks in August and September; special courses; and clinical assistantships for periods of three months. In the University of Aberdeen the Faculty of Medicine has approved a three months' course from April to June; and at St. Andrews a course was given in June by the staff of the James Mackenzie Institute for Clinical Research. Courses in special diseases can be obtained in London at a large number of special hospitals. Special note may be made of the London School of Tropical Medicine, which has now been incorporated in the new London School of Hygiene and Tropical Medicine; of the Liverpool School of Tropical Medicine; and of the Maudsley Hospital, Denmark Hill, S.E.5. In addition to these post-graduate courses at hospitals and schools, the Joint Tuberculosis Council organized this year a series of courses at various tuberculosis institutions, with a study tour in Norway last July.

It will be seen, therefore, that while a wide range of facilities exists for post-graduate study, there is no really large and prominent post-graduate school situated in the centre of London. There is no systematic linking up of the numerous facilities for study for the purpose of attracting students from all English-speaking countries. For this purpose an institution would seem to be required with a central office to which inquiries may be addressed, and from which advice and information may be given. If possible this office should belong to a school with teachers and regular teaching by lectures and clinical work, and with laboratories attached; the school should preferably be attached to a post-graduate hospital for all ordinary clinical and pathological work; arrangements should be made with special institutions for courses in advanced work; there should be a linking up with provincial centres for those who wish to study under a special teacher; and a centre for social intercourse should be part of the organization. The British Medical Association has helped in providing the last of these objects by encouraging the hostel at the Imperial Hotel. It remains to be seen how many of the other portions of the scheme will be embodied in the report of the committee of the Ministry of Health.

#### FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.

The Fellowship of Medicine has arranged regular courses in general medicine and surgery, including special departments, each lasting two weeks; they are held at intervals of six weeks, and the fee for each course is 3 to 5 guineas. Courses in diseases of chest, children, heart, nervous system, throat, nose and ear; dermatology; electrotherapy; gynaecology; proctology; psychological medicine; tropical medicine; urology and venereal diseases are given from time to time at the special hospitals in association with the Fellowship of Medicine. The Fellowship Programme contains a diary of the arrangements available for post-graduates in various general and special hospitals in London. Practical courses in obstetrics and child welfare are arranged throughout the year; the duration of each course is one week. Also, practical courses in anaesthetics can be arranged at any time. The programme for the immediate future includes a two weeks' course in general medicine and surgery, from September 20th to October 2nd, at the Westminster Hospital. There will also be special courses in infants' diseases at the Infants Hospital from September 13th to 25th; in ophthalmology at the Central London Ophthalmic Hospital from September 6th to October 2nd; in psychological medicine at the Bethlem Royal

Hospital from September 6th to October 2nd; and a course in electrotherapy at the Royal Free Hospital from September 22nd to October 13th. The offices of the Fellowship are, by kind permission of the Royal Society of Medicine, at No. 1, Wimpole Street, W.1 (telephone, Mayfair 2263). The secretary is in attendance daily from 10 a.m. to 5 p.m., excepting Saturday. The annual subscription for membership of the Fellowship of Medicine and Post-Graduate Medical Association has been fixed at a minimum of 10s.

#### WEST LONDON POST-GRADUATE COLLEGE.

The work of this institution is carried on at the West London Hospital, the first in London to devote its clinical material solely to the instruction of qualified medical men. The college started in 1895; it is provided with lecture, reading, writing, and class rooms, and accommodation of all sorts for the convenience of post-graduate students. The work of the college is eminently suitable for men in general practice and officers in the services who wish to revive their general clinical knowledge.

As for ward work, the students accompany the senior staff on their visits to the wards at 2.30 p.m. daily, and also go round with the resident medical officers in the morning. Out-patient work begins at 2 p.m. This department is large, and affords ample facilities for post-graduates to see and examine patients. There are the usual special departments. Post-graduates are appointed to act as clinical assistants for three or six months, no charge being made. Special practical classes are held in medicine, general practical surgery, gastro-intestinal surgery, medical and surgical diseases of children, analysis of blood and urine, cystoscopy, venereal diseases, tropical diseases, retinoscopy, ophthalmic operative surgery, and, when material is available, in operative surgery. The size of the classes is limited. A special clinic for the treatment of venereal diseases (male and female) is held every evening (Saturdays included) at 5.30. Graduates are admitted to the work of the clinic free, and certificates of satisfactory attendance and work are given.

Operations take place at 2 p.m. daily, the surgeons often availing themselves of the assistance of the graduates, and in any case making arrangements so that they can readily see what is going on. The anaesthetists give instruction in the administration of anaesthetics, including spinal analgesia, on the operating days, students being allowed to administer them under supervision, while special classes are held in each session. The pathological laboratory is in charge of a pathologist who attends every day.

Demonstrations are ordinarily given in the morning by the assistant physicians and surgeons, and by the medical and surgical registrars.

**Fees.**—Hospital practice, including all ordinary demonstrations and lectures, £1 11s. 6d. for one week, £4 4s. for one month, £7 7s. for two months, £9 9s. for three months, £15 15s. for six months, £23 12s. 6d. for one year, and £45 for a life ticket. Instruction in the administration of anaesthetics is given at the rate of £3 3s. a month.

The certificates of the school are recognized by the Admiralty, the War Office, the Colonial Office, the India Office, and the University of London (for higher degrees). A prospectus can be obtained on application to the Dean.

#### NORTH-EAST LONDON POST-GRADUATE COLLEGE.

The headquarters of this post-graduate school are situated at the Prince of Wales's General Hospital, Tottenham, N.15, in the midst of this densely populated North London district. It contains 200 beds, and is within a few minutes' walk of South Tottenham station, on the London, Midland, and Scottish Railway, and Seven Sisters and Tottenham Hale stations, on the London and North-Eastern Railway. It is readily accessible by electric tram from Finsbury Park and Hackney, and from Dalston, Edmonton, and other parts of North London.

The college is in association with the Fellowship of Medicine and Post-Graduate Medical Association, and is recognized by the Admiralty and India Office for the purpose of study leave, and by the University of London as a place for advanced study for the M.D. and M.S. degrees; the course of practical teaching of bacteriology is approved by the University of Cambridge for its Diploma in Public Health,

and there are ample arrangements for the convenience of men who are thus working, or who, being in active practice, are desirous of getting themselves into touch with modern methods. The hospital as a whole affords excellent facilities for qualified medical practitioners who wish to take part for a time in the work of an active general hospital, or to obtain special instruction in the several branches of medicine and surgery, since it is open to them to study diseases of the eye, ear, throat, nose, skin, fevers, children's diseases, psychological medicine, dental surgery, radiography, the application of electricity in disease, and the administration of anaesthetics. Throughout the sessions into which the year's work is divided, clinics, lectures, and demonstrations are given by members of the teaching staff. Operations are performed every afternoon of the week except Saturday. Special vacation or intensive courses are held at intervals throughout the year, each lasting two weeks, clinical instruction being arranged for each hour of each day.

*Fees.*—Two guineas for a three months' course of study in any one department, which may be begun at any time; a fee of 5 guineas admits to the whole practice of the hospital for a similar term (one month 2 guineas, and one year 10 guineas), and a perpetual ticket for the practice of the hospital may be obtained for 15 guineas.

The winter session will be opened about the middle of October as regards clinical lectures, but the clinical work of the hospital is carried on continuously.

Additional information can be obtained from the Dean of the Post-Graduate College, at the hospital, or at 19A, Cavendish Square, London, W.1.

#### NEWCASTLE-ON-TYNE.

For the year 1926-27 the following post-graduate courses have been arranged by the College of Medicine, Newcastle-on-Tyne (University of Durham):

1. General courses in clinical medicine, surgery, and pathology at the Royal Victoria Infirmary, meeting once weekly for ten weeks. One course will be held from October to December, and one from April to June.
2. Special courses of clinical instruction meeting once weekly for ten weeks in the following subjects: Gynaecology, diseases of the eye, diseases of the throat, nose, and ear, diseases of the skin, venereal diseases, neurology.
- Special courses in midwifery will be held at the Princess Mary Maternity Hospital.
3. An intensive course of fourteen days' duration in the early part of the Summer Vacation, 1927.
4. In addition to the regular post-graduate courses practitioners may attend the ordinary medical and surgical practice of the Royal Victoria Infirmary for specified periods.

#### COURSES FOR MEDICAL GRADUATES AT BRISTOL.

The University of Bristol provides courses of post-graduate study for practitioners. Details of set courses at the Royal Infirmary and General Hospital are announced locally. In addition, practitioners may become clinical assistants in medicine, surgery, or special subjects for periods of a month or more.

The university also holds courses of demonstrations in outlying centres in the West of England. Resident practitioners form themselves into a committee and consider the type and extent of demonstrations required. The university furnishes the lecturers and makes all the necessary arrangements. All inquiries should be addressed to the Director of Post-Graduate Studies, Pathological Department, Bristol University.

*Daily Post-Graduate Study.*—For those who are able to devote several hours each day to hospital practice the university offers special facilities for post-graduate work. Qualified medical practitioners may be appointed as clinical assistants for a period of one or more months. They may act as assistants, if times permit, in more than one department and in any of the hospitals during their period of study. They will be entitled to the use of the clinical laboratories and medical library, and have the right to attend in all departments, including operations, post-graduate and ordinary clinical demonstrations, and *post-mortem* examinations.

*Post-Graduate Clinical Work.*—Demonstration courses with weekly lectures are held during May, June, and July. All inquiries and applications for admission should be addressed to the Director of Post-Graduate Studies (Clinical Section), Pathological Department, University of Bristol,

who can be seen on any day by appointment at the Pathological Department.

Further information as to scholarships, curricula, and fees can be obtained from the Dean of the Faculty of Medicine, or the Registrar of the University, Bristol.

#### EDINBURGH POST-GRADUATE COURSES.

In connexion with the University and Royal Colleges post-graduate courses are arranged every year, from about the middle of July to about the middle of September, comprising: (a) This year a course in obstetrics and gynaecology was held from July 12th to August 6th; (b) a course on diseases of children from August 2nd to 7th. (c) a general medical course; (d) a general surgical course. Courses (c) and (d) extended for four weeks from August 9th to September 4th. Similar courses are held each year.

The course in obstetrics and instruction in clinical midwifery, obstetrics and gynaecological pathology, ante-natal clinics, etc.

The course on diseases of children comprises clinical demonstrations and systematic lectures dealing with the diagnosis and treatment of the common and important diseases met with in medical practice, and including the dieting of infants and children. The general medical course includes lecture demonstrations, and, where possible, practical instruction on medical anatomy, medical side-room work, examination of the blood, x-ray and electrical therapy, morbid anatomy, and *post-mortem* examinations; clinical instruction in medicine, diseases of children, diseases of the skin, and infectious diseases; and special instruction in the diseases and methods of examination of the nervous, circulatory, respiratory, alimentary, and renal systems, and in diseases of the ductless glands. The general surgical course includes lecture demonstrations on surgical anatomy, surgical pathology, and surgical x-ray diagnosis; clinical instruction in surgery at the Royal Infirmary and Royal Hospital for Sick Children; clinical instruction in venereal diseases; surgical out-patients, surgical and gynaecological operations and special instruction in abdominal and genito-urinary and other branches of surgery.

A series of special lectures, open to all graduates, is delivered thrice weekly, on subjects of general medical and surgical interest, including recent advances in treatment. Among the special courses also arranged are: examination of the blood, vaccine therapy, clinical chemistry, diseases of the ear, nose, and throat, and venereal diseases.

Particulars regarding the courses, dates of commencing, fees, etc., may be had on application to the Honorary Secretary, Post-Graduate Courses in Medicine, University New Buildings, Edinburgh.

#### POST-GRADUATE MEDICAL TEACHING IN GLASGOW.

Organized post-graduate medical teaching is available in Glasgow under the auspices of the Post-Graduate Medical Association. This association is composed of practically all the teaching institutions in Glasgow and the various teachers giving post-graduate instruction, and its business is managed by a board elected periodically by them. The chairman of the board is Principal Sir Donald MacAlister, Bt., and the vice-chairman Sir Hector C. Cameron. During the winter months special courses in various subjects are conducted, and from November till May there is a series of weekly demonstrations specially designed for local practitioners. A comprehensive scheme of clinical courses is carried out during the summer months, from June till October, and arrangements have also been made whereby a limited number of graduates may become attached to wards or out-patient departments nominally as clinical assistants for definite periods throughout the year. As such they work under the direct supervision of the physician or surgeon in charge, and carry out such detailed investigations as directed.

A general medical and surgical course is now held each year during the last two weeks of August and the first two weeks of September, which is arranged to include most of the subjects of interest to the general practitioner.

This year the course is being conducted from August 16th to September 11th. The forenoons are occupied with general medicine and surgical diagnosis and minor surgery, in the Victoria Infirmary and in the Western Infirmary. In the afternoons special subjects are dealt with in the special hospitals and in the special departments of the general hospitals, two subjects being dealt with each afternoon. On the four Saturday forenoons tuberculosis and infectious fevers are demonstrated at Ruchill Fever Hospital.

Further information may be had on application to Dr. James Carslaw, Secretary, Post-Graduate Medical Association, 6, Woodside Crescent, Glasgow, C.3.

#### AUSTRALIAN AND NEW ZEALAND MEDICAL ASSOCIATION.

The Australian and New Zealand Medical Association gives information and advice to medical visitors from the Commonwealth and Dominions with regard especially to attendance at special clinics, post-graduate work, and facilities for preparing for examinations such as the M.R.C.P., F.R.C.S. (England and Edinburgh), and the D.P.H., and also as to house appointments and clinical assistantships in London and the provinces. Information will also be given as to lodgings, sports, and social opportunities. All medical graduates or undergraduates born in Australia or New Zealand and resident in or visiting England are eligible to become members. The fee is one payment of 5s. Further information can be obtained from the joint honorary secretaries, Mr. E. T. C. Milligan, F.R.C.S., and Mr. Bedford Russell, F.R.C.S., 86, Harley Street, London, W.1.

## TROPICAL MEDICINE.

THERE are large and important schools of Tropical Medicine in London and Liverpool, and several universities and other examining bodies have instituted diplomas or degrees in the subject. The Colonial Office now expects all nominees for the Colonial Medical Service to pass through one or other of the two schools mentioned before their appointments are confirmed, and commercial firms engaged in tropical enterprise commonly demand from medical applicants for employment corresponding evidence of special knowledge. Information with regard to these schools and diplomas and degrees follows.

#### DIPLOMAS AND DEGREES.

**LONDON UNIVERSITY.**—Tropical medicine is one of the six branches in which the M.D. degree may be obtained. The regulations relating to the curriculum and examination correspond to those applying to the other branches.

**LONDON CONJOINT BOARD.**—This body grants a diploma in tropical medicine to candidates after an examination held in the months of February and July. Candidates must present evidence of having attended, subsequently to obtaining a registrable qualification in medicine, surgery, and midwifery, (1) practical instruction in pathology, protozoology, helminthology, entomology, bacteriology, and hygiene in relation to tropical medicine, in an institution recognized for this purpose, during not less than five months; (2) the clinical practice of a hospital recognized for the study of tropical diseases during not less than five months. These conditions may be modified in the case of candidates who have had practical experience in tropical countries. The fee for admission to the examination is £9 9s. The Board also grants diplomas in public health, in psychological medicine, in ophthalmic medicine and surgery, and in laryngology and otology. Candidates must hold a medical qualification registrable in the United Kingdom, or be graduates in medicine of an Indian, Colonial, or foreign university. Particulars and conditions of admission to these examinations, fees, etc., may be obtained from the Secretary of the Examining Board, Examination Hall, Queen Square, Bloomsbury, London, W.C.1.

**UNIVERSITY OF LIVERPOOL.**—A diploma in tropical medicine is given by this university to students who have been through the courses provided by the Liverpool School

of Tropical Medicine and have passed the examination held twice yearly by the university examiners. The subjects of examination are (a) tropical pathology, parasitology, and entomology; (b) tropical and applied bacteriology; (c) tropical hygiene and sanitation; (d) tropical medicine, including etiology, symptoms, diagnosis, and treatment of tropical diseases. Further information can be obtained from the Dean of the Faculty of Medicine, University of Liverpool. A diploma in tropical hygiene (D.T.H.) has recently been established. The subjects of examination are bacteriology, chemistry (including meteorology and climatology), entomology, protozoology and helminthology, tropical sanitation (including sanitary engineering), practical sanitation. Fee for the course, £15.

**UNIVERSITY OF CAMBRIDGE.**—This university grants a diploma in tropical medicine and hygiene to any person whose name has been on the *Medical Register* for not less than a year provided that he passes the examination of the university in this subject. Previous to admission to the examination he must produce approved evidence that he has studied pathology (including parasitology and bacteriology in relation to tropical diseases), clinical medicine, and surgery at a hospital for tropical diseases, and hygiene and methods of sanitation applicable to tropical climates. Examinations are held in January and August each year and last four days. The fee for the examination (which is divided into two parts) is 10 guineas for each part on admission or readmission. Application for further information should be made to Dr. G. S. Graham-Smith, Pathological Laboratory, Cambridge, or Mr. J. E. Purvis, Public Health Chemical Laboratory, Medical School, Cambridge.

#### SCHOOLS.

##### LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE.

##### *Division of Tropical Medicine and Hygiene (University of London).*

The London School of Tropical Medicine, formerly under the auspices of the Seamen's Hospital Society, was on August 1st, 1924, incorporated by Royal Charter in the London School of Hygiene and Tropical Medicine, and the work of the school continues as the Division of Tropical Medicine and Hygiene of the new institution. By the generosity of the Rockefeller Foundation a large sum has been provided for new buildings in Bloomsbury, but for the present the work of the school is carried on as heretofore in the Seamen's Hospital Society's buildings at the Hospital for Tropical Diseases, Endsleigh Gardens, W.C.1, where the specially equipped laboratories, museum, library, and clinical facilities afford excellent opportunities to the student and others who may be desirous of studying diseases incidental to tropical climates before entering the services or going abroad. In the wards of the Hospital for Tropical Diseases are to be found cases such as may be met with in actual practice in the tropics. There are two courses in the year, each lasting twenty weeks, beginning October 4th, 1926, and March 14th, 1927, respectively. The course is so arranged as to equip men for the D.T.M. and H. of the Conjoint Board. There are also advanced courses and a special course in parasitology for D.P.H. students and for the first part of the D.T.M. and H.Camb. Clinical instruction is also provided for the second part of the D.T.M. and H.Camb. Tropical medicine is a sixth alternative subject for the M.D. of the University of London, and the school curriculum is adapted to afford facilities for candidates desirous of taking the M.D. in this subject. Further information may be obtained from the Secretary, London School of Hygiene and Tropical Medicine, 23, Endsleigh Gardens, London, W.C.1.

##### LIVERPOOL SCHOOL OF TROPICAL MEDICINE.

This school is affiliated with the University of Liverpool. The university now grants diplomas in tropical medicine (D.T.M.) and in tropical hygiene (D.T.H.).

Two full courses of instruction, each lasting about eleven weeks, are given every year for the D.T.M., commencing respectively October 1st (Autumn term), and January 7th (Lent term); and two courses of the same duration for the D.T.H., beginning on January 7th and April 22nd (Summer term). The D.T.H. can only be taken by those

## PSYCHOLOGICAL MEDICINE.

who have obtained the D.T.M. Students who do not desire to take the diploma examinations held by the university at the end of each term are given a certificate if attendance has been satisfactory.

*Fees.*—(1) For the D.T.M. or D.T.H. course, 15 guineas. (2) For the diploma examinations, 5 guineas. An extra charge of one guinea is made for the use of a microscope if required.

The new laboratories of the school adjoin the university and the tropical ward of the Royal Infirmary. The dimensions of the building are 162 feet in maximum length by 84 feet in width. In addition to the basement, in which are accommodated the photographic department and large storage rooms, there are four floors. The ground floor has: (1) lecture theatre, with accommodation for about seventy students; (2) library; (3) a spacious museum with preparation room adjoining. The first floor has twelve rooms, in which are housed the Departments of Tropical Medicine and Entomology. The second floor has the main class laboratory, 69 feet by 58 feet, excellently lighted; and three other rooms, devoted to the Department of Parasitology. The third floor has a large research laboratory and two research rooms. On the roof is an insectarium, a mosquito-proof house, and other accommodation.

Since its foundation the school has dispatched to the tropics thirty-two scientific expeditions, many of the workers having been taken from among its students. Work done by the staff has been published in twenty-one special memoirs—in the *Annals of Tropical Medicine and Parasitology*, issued by the school, and in numerous articles in the scientific press.

The school has also two laboratories in the tropics: The Manóas Research Laboratory in Brazil; and the Sir Alfred Lewis Jones Tropical Laboratory in Sierra Leone, which was opened on January 10th, 1922, and is staffed by the school. Further information may be obtained from the Honorary Dean, School of Tropical Medicine, Pembroke Place, Liverpool.

## PSYCHOLOGICAL MEDICINE.

It cannot be impressed too strongly upon the medical student that a knowledge of mental disorder is just as essential as a knowledge of the other forms of disease which he will be called upon to treat in the routine of general practice. It must be understood that by the term "mental disorder" is not only meant those severe forms which are to be found in asylums, but the term also includes mental defects of all grades, nervous, difficult, and backward children; the mild and often unrecognized psychoses; and also the various types of psychoneurosis. Such disorders provide the general practitioner with a large proportion of his most difficult cases, and he will find a good knowledge of mental disorder invaluable in his work. Apart from general practice, the student who proposes to take up a career in the prison service or, still more importantly, the school medical service, will find a knowledge of psychological medicine an almost essential part of his equipment.

*Instruction.*

Though at the present time the instruction given to the student is far from adequate to supply the knowledge of mental disorder requisite for the needs of the general practitioner, the facilities for the study of psychological medicine in the general hospitals are now much greater than in former years. Thus many of the teaching hospitals have out-patient departments for the treatment of mental cases, and in some of these hospitals special lectures are given on psychopathology. These facilities need not be utilized by the student, however, and the compulsory part of the curriculum is confined to formal lectures and a few attendances at some mental hospital. Here the student is apt to see mainly the terminal states of mental disorder and is also apt to gain the impression that mental disorder is necessarily related to segregation and custody. We would therefore impress upon him the importance of attending the out-patient department for mental disorders, where he will be able to observe the mild and early cases such as he will hereafter meet with in general practice.

A scheme is now in actual operation at the Middlesex Hospital in which a small number of mental cases are treated in the hospital as in-patients. This is an important move from the teaching point of view, because the student will gain true insight into the relation between mental disorder and medicine as a whole, and he will realize that it is a form of illness to be studied with other diseases and to be treated along similar lines.

In London post-graduate courses of instruction of a comprehensive kind are given at the Maudsley Hospital, and at Bethlem Hospital; and at the National Hospital, Queen Square, courses are arranged to meet the requirements for the diploma in psychological medicine in regard to nervous diseases. Courses in mental deficiency are arranged by the University of London. There are also post-graduate courses at the Universities of Glasgow, Cambridge, Edinburgh, Birmingham, Leeds, Manchester, Durham, and elsewhere.

*Diplomas.*

Those who are taking up psychiatry as a career will find it desirable to obtain a diploma in psychological medicine. Such a diploma is not at present compulsory for a permanent position on the staff of all mental hospitals, but it will probably become so in course of time, just as it is now essential to obtain the D.P.H. if a career in public health is contemplated. Psychiatry is one of the branches of medicine which candidates for the M.D. degree of the Universities of London and Edinburgh can take up, and, in addition, diplomas in psychological medicine, to which reference has been made, can be obtained from the Universities of Cambridge, London, Edinburgh, Durham, Leeds, Manchester, Dublin, and the National University of Ireland, and from the Conjoint Board in England. The Medico-Psychological Association of Great Britain and Ireland also grants certificates of proficiency after examination, and encourages the study of psychiatry by the offer of prizes for original and research work.

The requirements for a diploma differ to some extent in the various universities and colleges, but the following model scheme suggested by the Medico-Psychological Association, and already adopted by the Royal College of Physicians of Ireland, will give an indication of the scope of the examination for a diploma.

*Model Scheme for a Diploma in Psychological Medicine.*

1. The candidate must be already a registered medical practitioner.
2. The candidate may present himself for examination on the subjects detailed under Part I of the curriculum (see para. 4) immediately he has concluded the prescribed courses of instruction, or can produce such other evidence of diligent study of the subjects to be examined upon as may be demanded. Part I must be passed by special permission at least three months prior to entering for examination on Part II of the curriculum.
3. The candidate may not present himself for examination on the subjects detailed under Part II of the curriculum for not less than two years. He must, subsequently to qualification, have been in the practice of an approved mental hospital for not less than two years, or have attended for six months at a hospital, mental or general, for clinical instruction in psychological medicine, and subsequently held a resident appointment at an approved mental institution or mental wards of a general hospital for not less than six months. In both cases he must produce a certificate from a recognized source that he can apply his theoretical knowledge, and has practical acquaintance with, and is well and adequately versed in, the current clinical methods of examination and treatment of nervous and mental disorders. In the case of mental deficiency the certificate should include a practical knowledge of the various intelligence tests and other methods of ascertaining the degree of mental defect. He must also produce evidence of having attended, subsequently to qualification, courses of lectures, demonstrations or other evidence of diligent study of the subjects upon which he presents himself for Part II of the examination, as may be demanded.
4. Curriculum: Part I—(a) Anatomy, histology and physiology of the nervous system, including the autonomic system, anatomy and physiology of the endocrine glands, chemistry and cytology of the cerebro-spinal fluid. (b) Psychology, systematic and experimental. Part II—(a) Morbid anatomy, histology and physiology of the systems mentioned under Part I, (a) *post-mortem*; (c) psychiatry technique; (b) neurology and clinical neurology; (c) psychiatry (including the psychoneuroses), clinical psychiatry and the medico-legal relationships of mental disorders and mental deficiency. In addition, the candidate for Part II will need to show special knowledge of any one subject, to be selected by him from the subjects comprising Part I or Part II, or may choose to be examined in any one of the following subjects: (d) Mental

deficiency and the mental disorders of childhood and adolescence, and the duties of school medical officers in relation thereto. (c) Bacteriology as applied to mental and nervous disease. (f) Psychopathology and psychotherapy. (g) The principles of diet, vitamins, and basal metabolism, and their application. (h) Eugenics and vital statistics. (i) Criminology and the jurisprudence of criminal responsibility.

5. The diploma, by request, may be endorsed that special knowledge has been shown in the subject selected.

6. It is suggested that any compulsory attendance at lectures or demonstrations and clinical courses should be limited to the subjects detailed for Part II, and that the course for Part I or Part II should not exceed eight weeks.

#### *Mental Hospital Appointments.*

Those who take up psychiatry as a career work as medical officers of public or private mental hospitals or similar institutions. Except in the larger institutions, such as those under the control of the London County Council, where a number of the medical officers are allowed to live out if married, the medical staff are resident officers, having board, lodging, etc., either in the hospital itself or a residence in the grounds. Junior assistant medical officers receive about £300 to £400 per annum, and senior assistant medical officers about £500 to £700, in both cases with board, lodging, laundry, etc., in addition; if married, the board, etc., is commuted for cash. As the mental hospitals are under local control the salaries vary much in different asylums. Medical superintendents, whose pay commonly ranges between £800 and £1,500 per annum, are provided with a house in the grounds of the hospital and draw various allowances.

Since the passing of the Asylum Officers' Superannuation Act of 1909, all officers and others of the established staff of a public (county or borough asylum) mental hospital may retire at the age of 55 on a pension varying from one-half to two-thirds of the value of their pay and emoluments, or one-fiftieth for every year served, paying as contribution 3 per cent. of the value of their appointments annually. This very favourable prospect may not appeal to junior practitioners joining the services, but will eventually prove to be a valuable asset.

#### *Prospects in the Public Service.*

Appointments to the public mental hospitals are made by the visiting committees, and in most cases only the junior posts are open to those who have not had previous experience in psychiatry. Since the public mental hospital service is a local and, except indirectly, not an imperial one, the promotion tends to be slow and uncertain, and the higher positions are not always advertised and thus thrown open to competition. For this and other reasons mental hospital work has undoubtedly not been in favour with newly qualified men in years past, but the general conditions of service have tended to show a progressive improvement and will in all probability continue to do so in the future.

Both the British Medical Association and the Medical Psychological Association are working separately and together to improve present conditions of service, and have, for example, already removed the "celibacy" objection to the service. The salaries have also been considerably increased, especially in the junior ranks, and contrast favourably with those which were paid before the war. During the next few years considerable progress may be anticipated in the conditions under which the insane are treated. The asylums will tend to develop an atmosphere approximating more closely to that of the general hospitals. If these most desirable changes are brought about, the mental hospital service will become more attractive, and will afford greater opportunities for the medical graduate who proposes to specialize in psychiatry.

It may be said that while routine, administrative, and clerical work bulk largely in mental hospital duties, as they do in other public medical services, there is ample material, time, and scope for purely medical work and research—difficult as the subject may be—in psychiatry as one of the branches of medicine open to young graduates. A change in the lunacy law, in which power was given to local authorities to make provision for the treatment of early and acute cases of mental disorder without certification, would do much to make psychiatric work more attractive

to medical men. If this alteration in the law were made, hospitals, either in the precincts or the grounds of the county or borough mental hospitals, or in adjacent towns, would be erected in the course of time, or wards in general hospitals might be utilized for the same purpose. Such clinics would render appointments in mental hospitals more attractive because the work would be entirely free from the custodial aspects of mental disorder, and attention could be given by the physician to purely medical problems without irksome legal restrictions.

#### MAUDSLEY HOSPITAL, DENMARK HILL.

A number of courses of instruction for the Diploma in Psychological Medicine have been given at the Maudsley Hospital, the details of the last course being as follows: The course consisted of two parts, Part I being conducted by the late Sir Frederick Mott, Dr. F. Golla, and Dr. Henry Devine. Sir Frederick Mott gave eight lectures on the anatomy of the nervous system, followed by practical instruction and demonstrations on methods of staining nervous tissue and preparing it for microscopical examination; microscopic sections were distributed, illustrating the principal diseases of the nervous system for mounting as a permanent collection. Dr. Golla gave eight lectures on the physiology of the nervous system, followed by practical instruction and demonstrations on physiological chemistry (including the chemistry of the nervous system, physico-chemical methods, blood and urine analysis, and gastric contents analysis) and practical physiology (including the recording of reflexes and tremors in man and the action of drugs on the autonomic system). Similarly, Dr. Devine gave eight lectures on psychology, followed by practical instruction and demonstration of psycho-physical methods and memory and intelligence tests. In Part II of the course Sir Frederick Mott gave six lectures on the pathology of mental diseases, including brain syphilis, its symptomatology and treatment. Dr. Bernard Hart gave eight lectures on the psychoneuroses. Sir Frederick Mott and Dr. F. Golla gave twelve clinical demonstrations in neurology; the first six demonstrations were given by Dr. Golla at the Hospital for Paralysis and Epilepsy, Maida Vale. Dr. F. C. Shrubbsall gave eight lectures on the practical aspect of mental deficiency. The late Dr. W. C. Sullivan, medical superintendent of Broadmoor Asylum, gave four lectures on crime and insanity. Dr. E. Mapother gave a course of lectures on the differential diagnosis and treatment of mental disorders. The fee for the whole course (Part I and Part II) was 15 guineas, or for either part separately 10 guineas; for one single series of lectures in Part I the fee was 4 guineas, and in Part II 2 guineas. Inquiries as to lectures, etc., should be addressed to the director of the pathological laboratory, Maudsley Hospital, Denmark Hill, S.E.5.

#### BETHLEM ROYAL HOSPITAL.

A course will be held at Bethlem Royal Hospital, commencing on September 13th, of lectures and practical instruction for the Diploma in Psychological Medicine. It is proposed in future to give two courses each year—an autumn session of intensive character, commencing in September, and completed in early December, and a spring session, commencing in the middle of January and completed in the middle of April. Each course consists of two parts: Part A includes lectures and demonstrations on the anatomy, histology, and physiology of the nervous system, with lectures on psychology and demonstrations in experimental psychology. Part B comprises lectures and clinical demonstrations in psychology, including lectures and demonstrations in the morbid anatomy of the nervous system, a series of lectures, with clinical demonstrations, on different branches of psychological medicine, and lectures, with clinical demonstrations, on mental deficiency. Entrants for the course who pay a composition fee of 15 guineas may, if due notice is given, attend either Part A or Part B of one course and postpone the other part until the next session. An entrant who wishes to attend one part only pays a fee of 10 guineas. An entrant who takes the complete course can attend the general clinical practice of the hospital on payment of 5 guineas for six months, or 10 guineas for one year, but an entrant

who does not take either part of the course and desires to attend the clinical practice of the hospital must pay a fee of 5 guineas for each three months of attendance. To enable post-graduates to obtain special experience in this branch of medicine clinical assistants are appointed from time to time. Further particulars may be obtained from the physician-superintendent, Bethlem Royal Hospital, S.E.1.

#### NATIONAL HOSPITAL, QUEEN SQUARE.

A post-graduate course, which fulfilled the requirements of the regulations for the Diploma in Psychological Medicine in regard to instruction in nervous diseases, was held at the National Hospital, Queen Square, Bloomsbury, W.C.1, in May and June, and other courses will be duly announced. Lectures on the pathology of the nervous system and various clinical lectures were delivered and demonstrations were given, and out-patient clinics were held at the hospital on the afternoons of Mondays, Tuesdays, Thursdays, and Fridays. An inclusive fee of 9 guineas was charged for the whole course, but any part of the course could be taken separately at a special fee. A special arrangement was made for those unable to attend the whole course, and for details applications should be made to the dean of the medical school. Similar courses are held three times a year—namely, February, May, and October. Special arrangements are made throughout the year for work in the laboratory. Fees are payable to the secretary of the hospital on entering for the course.

#### THE TAVISTOCK CLINIC FOR FUNCTIONAL NERVE CASES.

Courses in modern psychotherapeutic methods for the treatment of "nervous breakdowns" can be obtained at the Tavistock Clinic, 51, Tavistock Square, W.C.1; and those who want to specialize in this treatment can obtain clinical assistantships. The methods of the clinic comprise a full and sympathetic investigation of the patient's history, sometimes dream analysis, suggestion and mental exercises where necessary, and re-education of the patient to fit him to deal with his difficulties. The director of the clinic is Dr. H. Crichton Miller, the deputy director Dr. J. R. Rees, and there is a children's department under the directorship of Dr. W. A. Potts.

## THE PUBLIC HEALTH MEDICAL SERVICES.

THE central authority to secure the preparation, effective carrying out, and co-ordination of measures conducive to the health of the people, and to promote research work and a proper training of persons for health services, is the Ministry of Health.

For the purpose of local public health administration the whole of England and Wales is divided into counties, county boroughs, boroughs, and urban and rural sanitary districts. The administrative County of London, exclusive of the City of London, is divided into twenty-eight metropolitan boroughs.

The public health medical services for Great Britain embrace between three and four thousand medical men and women who give whole-time services, and in addition a large number who give part-time services. The medical officers appointed for these services may be either medical officers of the Ministry of Health for England or of the corresponding Boards of Health for Scotland and Wales; or—and these form the large majority—they may be medical officers appointed by the many local public health authorities. These latter appointments include: medical officers of health, tuberculosis medical officers, maternity and child welfare medical officers, venereal diseases medical officers, and school medical officers—for the education authorities must now be regarded as health authorities in respect to the health interests of the school child. By the larger public health authorities assistant medical officers are also appointed, and these posts often serve as stepping-stones to the higher offices as vacancies, which are required to be advertised, occur.

#### THE MEDICAL SERVICES OF THE CENTRAL AUTHORITY.

The Medical Department of the Ministry of Health for England has been organized under the control of a chief medical officer. It contains six sections, with a senior medical officer at the head of each, and altogether fifty medical officers. The sections deal with: general health and epidemiology, maternity and child welfare, tuberculosis and venereal diseases, the supervision of food supplies, and sanitary administration in relation to infectious diseases. There is, in addition, a section concerned with insurance practitioners. Appointments to these posts are not as a rule open to public competition; they are made by the Minister of Health. They are civil service appointments, and come under the civil service superannuation scheme. Medical officers are also employed by the corresponding Boards of Health for Scotland and Wales.

#### MEDICAL OFFICERS OF HEALTH.

The duties of the medical officer of health are to inform himself upon all influences affecting, or threatening to affect, injuriously the public health within his district; to advise his sanitary authority upon all matters relating to health; and to perform all the duties imposed upon him by statutes, by-laws, and regulations. He must prepare and submit to his local authority special and annual reports; give immediate information to the Ministry of Health of any serious outbreak of disease; and, subject to the instruction of his sanitary authority, he shall direct or superintend the work of sanitary inspection.

By the Sanitary Officers Order, 1926, no person is qualified to be hereafter appointed or reappointed as a medical officer of health of any district or combination of districts unless, in addition to the qualifications prescribed by any statute, he is also either registered in the *Medical Register* as the holder of a Diploma in Public Health, Sanitary Science, or State Medicine, or has had not less than three years' previous experience of the duties of a medical officer of health.

The Public Health (Officers) Act, 1921, which was promoted by the British Medical Association, provides that a whole-time medical officer of health of a county borough or urban and rural district in England and Wales, a part of whose salary is contributed by the Exchequer, shall not be appointed for a limited period, and shall not be removed from his office except by or with the consent of the Minister of Health. A similar security of tenure also applies to the medical officers of health of county councils and of London boroughs.

Under the Sanitary Officers Order, 1926, a medical officer of health who does not devote his whole time to the duties of his office, but a portion of whose salary is obtained from Exchequer grant, may be appointed without limit of time; in which case he cannot be removed from office without the consent of the Minister. If he is appointed for a specified term, say one year, he continues to hold office from year to year unless the Minister consents to his removal. Where the electing body pays the whole of the salary of a medical officer of health he may be dismissed from office without reference to the Minister of Health.

A considerable number of authorities have now adopted the Local Government and Other Officers Superannuation Act, 1922. Under this Act if an officer is incapacitated by ill health after ten years of service, or if he has reached 65 years of age, he is entitled to superannuation on the following scale: after ten years' service, 10/60 of the average salary which he received during the last five years of employment; after eleven years, 11/60, and so on up to a maximum of 40/60 after forty years or more of service. The Act, however, remains permissive, and it fails to make due allowance, in computing service for purposes of superannuation, for the more advanced age, as compared with other officers, at which the medical officer of health can enter the public service. In these two respects the position reached falls short of that for which the British Medical Association has been working for many years.

In Scotland the position is different in some respects. The central authority is the Board of Health, with a staff of medical officers for insurance work. Under the Public

Health (Scotland) Act, 1897, no one can be appointed as medical officer of health for any area unless he possesses the Diploma in Public Health. No medical officer can be removed from office except with the sanction of the Board of Health. A "proper" salary must be paid, and the local authority may not bring about the resignation of the officer by indirect means, such as reducing the salary or attaching conditions to the appointment. The Act says nothing about superannuation or the age of retirement.

#### SCHOOL MEDICAL OFFICERS.

School medical officers are appointed by local education authorities. Primarily their duty is to detect among the children attending the public elementary schools any physical or mental defect which may retard education, and to inform their parents of its existence. Most approved schemes of medical inspection include systems of work which facilitate the task of parents in obtaining for their children the necessary treatment, check the results of this treatment, and keep each defective child under skilled observation both at home and at school until it has passed altogether out of the education authorities' hands. Indeed, it is now the practice for the education authorities themselves to provide for certain ameliorative work, notably the prescription of glasses where necessary, the removal of adenoids and tonsils, and treatment in connexion with certain diseases of the skin. The general object of all schemes alike is to make the inspection imposed by law of benefit, not merely to the individual child, but to the community at large, by preventing conditions which lead to the existence of a large proportion of inefficient citizens among the adult population. The work is so related to that of medical officers of health that, as a rule, the senior school medical officer fills both appointments, his work, when necessary, being supplemented by that of whole- or part-time assistants. A Diploma in Public Health is almost always required of those entering the school medical service.

In Scotland, while the statutory authority for the work of the school medical service is different, the effect is broadly the same.

#### TUBERCULOSIS MEDICAL OFFICERS.

A tuberculosis medical officer is a whole-time officer with special training and experience in tuberculosis work, and of a suitable age and attainments to command general confidence. In England and Wales such officers are appointed by county councils and county borough councils, and their duties are to carry out the work of diagnosis of tuberculous patients, to advise as to treatment, and to take charge of the work of tuberculosis dispensaries and sanatoriums where these are in operation. The work under tuberculosis schemes is co-ordinated with the general public health work of local authorities, and so the medical officer of health is often appointed as the chief tuberculosis officer when a special tuberculosis officer is on the staff of the local authority. The arrangements in Scotland are very similar.

#### MATERNITY AND CHILD WELFARE MEDICAL OFFICERS.

Any public health local authority, however small, may make arrangements for maternity and child welfare work within its area, although very generally the smaller local authorities are embraced in county council schemes. For the schemes of the smaller local authorities the services of a part-time medical officer are obtained when the medical officer of health does not himself undertake the duties; but for the larger schemes special whole-time appointments are made. The maternity and child welfare medical officer is responsible for the work at the centres provided and for directing the home visitations; and the whole of his work is closely co-ordinated with the other branches of public health work directed by the medical officer of health.

Much of this work was commenced in different parts of the country by voluntary organizations; some of it still remains in their hands, and is only loosely linked up with the public health local authority; but the tendency is for the whole of it to be undertaken by the local authorities. A large number of women medical officers have been appointed to these posts during recent years.

#### VENEREAL DISEASES.

Schemes for the diagnosis and treatment of venereal diseases are provided and administered by county councils and county borough councils. In some cases the officer is on the staff of the medical officer of health, and in others he is an independent official. Special knowledge and practical experience in the treatment of venereal diseases are essential. The officer appointed for either whole-time or part-time services works at one or more clinics, and also gives instructions and assistance in the treatment of venereal diseases to general practitioners, who are allowed to attend the clinics.

#### REMUNERATION FOR SERVICES.

If we are to have skilled and highly trained medical officials of public authorities it is of course essential that they should receive salaries commensurate with their attainments and bearing a reasonable relation to the amount of time and money that have been expended in fitting them for their important and responsible duties. At present, no standard scale of remuneration for whole-time services has been adopted by public health authorities, although the British Medical Association and the Society of Medical Officers of Health—and more recently the Ministry of Health—have endeavoured to bring this about.

The present-day rate of remuneration for the whole-time services of a medical officer of health may be said to vary from £700 to £2,000 per annum, according to the dimensions of the population served and the officer's experience; while the maximum salaries of the principal officers of the allied medical services are somewhat lower. The whole-time medical officer working under a senior medical officer in most cases receives a commencing salary of £600 per annum, with bonus in some cases.

There are good prospects of the general adoption in the near future of a recognized scale of remuneration, which will provide a minimum commencing salary of £800 for a chief medical officer of health, of £750 for a chief medical officer of the allied medical services, and of £600 for all medical officers working under senior medical officers—when the officers are not resident in an institution provided by the local public health authority and when they give their whole-time services.

#### THE REGULATIONS FOR THE DIPLOMA IN PUBLIC HEALTH.

##### *The Examination.*

By the Regulations or Rules of the General Medical Council, which came into force on January 1st, 1924, the examination for the D.P.H. is divided into two parts, and no candidate is allowed to sit for the final part of the examination until two years have elapsed since a registrable qualification was obtained. The object of this two years' interval is "to provide opportunity for candidates for the Diploma or Degree in Sanitary Science, Public Health, or State Medicine, to pass from the state of pupilage to that of responsible practitioners, to give mature consideration to the obligations and duties involved in the work of the Public Health Service, and to acquire direct experience of medical work in a responsible capacity either in practice or in hospital or laboratory appointments."

The examination is both written and oral, and must include practical examination in bacteriology and chemistry (Part I) and in infectious diseases, food inspection, inspection of premises, dwellings, factories, workshops, schools, etc. (Part II).

Any candidate from the Dominions who possesses qualifications registrable in this country is eligible as a candidate for the examination, given that he has received such a course of training as that defined by the Regulations, at an institution which is approved by the General Medical Council.

##### *The Curriculum for the Diploma in Public Health.*

The curriculum must extend over a period of twelve months; and a candidate is admitted to either part of the examination after he has completed the prescribed course of instruction in the subjects thereof. At least five months

must be given to practical laboratory instruction in an institution approved by the licensing body, in the subjects:

(1) Bacteriology and parasitology, including entomology, especially in relation to diseases of man and to those diseases transmissible to man from the lower animals (180 hours of such instruction is required).

(2) Chemistry and physics in relation to public health (90 hours of such instruction is required).

(3) Meteorology and climatology (10 hours of such instruction is required).

Therefore at least 280 hours of practical instruction, extending over a period of at least five months, is demanded before a candidate is eligible for Part I of the examination.

For a candidate to become eligible for Part II of the examination he must first receive instruction in:

(1) Principles of public health and sanitation (for approximately 30 hours).

(2) Epidemiology and vital statistics (approximately 20 hours).

(3) Sanitary law and administration, including public medical services (approximately 20 hours).

(4) Sanitary construction and planning (approximately 10 hours).

(5) Every candidate must also have made thirty attendances, of not less than two hours in each week of a three-months period, at the clinical practice of a recognized hospital for infectious diseases; and he must have received instruction in methods of administration.

(6) Every candidate must produce evidence that he has, during a period of not less than six months, been engaged in acquiring a practical knowledge of the duties, routine and special, of public health administration under the supervision of a medical officer of health, who shall certify that the candidate has received, from this officer or other competent medical officer, during not less than three hours on each of sixty working days, practical instruction in these duties, and those relating to:

(a) Maternity and child welfare service;

(b) Health service for children of school age;

(c) Venereal diseases service;

(d) Tuberculosis service;

(e) Industrial hygiene;

(f) Inspection and control of food, including meat and milk.

Certificates of having received the prescribed instruction in public health administration must be given by a medical officer of health who devotes his whole time to public health work; or by the medical officer of health of a sanitary area having a population of not less than 50,000; or in Ireland by the medical superintendent officer of health of a county or county borough having a population of not less than 50,000.

#### *Training Centres for the Diploma in Public Health.*

Most of the universities of Great Britain and Ireland are training centres for the Diploma in Public Health. The University of London provides an M.D. in State Medicine to its own M.B., B.S. graduates.

In London at the present time there are fewer training centres for the D.P.H. than formerly. Candidates who desire to train in London can do so at University College and the Royal Institute of Public Health; and also at the Medical Schools of St. George's and Middlesex Hospitals when a sufficient number of candidates apply for the training.

## THE PUBLIC SERVICES.

### THE NAVY, ARMY, AIR FORCE, AND INDIAN MEDICAL SERVICES.

THE Medical Departments of the Royal Navy, of the Army, and the Indian Government normally employed between them before the war some 3,000 medical men, and vacancies in the ranks of these services were filled by offering commissions for competition once or more each year. In the abnormal circumstances arising out of the war and the period following it the usual regulations for recruiting the permanent medical staff of these services were, for the most part, in abeyance, and the newly formed Royal Air Force Medical Service also has depended largely upon short-service commissions for the maintenance of its medical personnel.

Meanwhile, recruitment for the Royal Naval Medical Service and for the Royal Army Medical Corps was seriously prejudiced by disadvantageous terms and conditions of service generally, and in particular by hardships inflicted under new regulations upon certain groups of senior officers. Continued representations were made by the

British Medical Association, but without avail, and it is only lately that its efforts on behalf of these services have begun to bear fruit in the manner indicated below. The often repeated refusal to remedy grievances imposed upon the Association the distasteful duty of issuing warnings to newly qualified practitioners; but now that the Government has changed its attitude the Association will use every endeavour to assist the Admiralty and the War Office in obtaining the candidates they need. In securing the improved terms which it has pressed upon the authorities the Association has gained a very notable success.

#### *Improved Terms and Conditions.*

As a result of the recommendations of the Interdepartmental Committee on the Medical Branches of the Fighting Services, before whom the British Medical Association gave evidence early this year, substantial increases in the rates of pay and retiring gratuities, and improved conditions of retirement for officers of the Royal Army Medical Corps, were embodied in a Royal Warrant issued by the War Office on June 29th last.<sup>1</sup> Simultaneously the Air Ministry announced improvements in the conditions of service and emoluments of medical officers of the Royal Air Force. The Admiralty also issued an Admiralty Fleet Order prescribing improved terms and conditions of service for medical officers R.N., and the India Office followed with revised terms of special recruitment for officers of the Indian Medical Service.

The changes, generally, take effect from July 1st, 1926, or (in the case of naval officers) "as soon afterwards as the necessary arrangements can be made." They were foreshadowed by the Prime Minister in his statement in the House of Commons on June 15th that the Government had considered the report of the committee appointed last autumn to consider questions relating to pay and other matters affecting recruitment of medical officers in the medical branches of the fighting services, and had decided to give effect forthwith to the committee's recommendations.

The British Medical Association, after examination of the revised terms, is satisfied with the new rates of pay and conditions of service for the R.N.M.S., the R.A.M.C., and the R.A.F.M.S.;<sup>2</sup> and in fulfilment of its desire to assist in recruiting these services we publish below the full particulars of each which have been supplied at our request by the Admiralty, the War Office, and the Air Ministry.

In regard to R.A.M.C. officers, whose particular difficulties have engaged the special attention of the Association during recent years, the increases in the rates of pay and retiring gratuities are substantial, as will be seen if the new rates are compared with the old rates promulgated by Royal Warrant after the war. But the new rates, like the old, are subject to the 5½ per cent. reduction owing to the decrease in the cost of living. The increases in the pay of R.A.M.C. officers do not begin until after six years' commissioned service, but from that time onwards, especially in the rank of major, very much has been done to make the service more attractive. One of the chief grievances was the fact that a major, after three years in that rank, or fifteen years' commissioned service, got no increase of pay until he was promoted lieutenant-colonel, a promotion which might possibly not take place until he had as much as twenty-four years of service. The new Warrant gives him a steady increase of pay, not only after fifteen years' service, but also after eighteen or twenty years' service. The ranks senior to that of major also participate in very substantial concessions. The retiring gratuities of a major after three and six years' service are now perhaps so great as to induce officers to retire before they become eligible for a pension, but in that case it is hoped that they will only make room for a large influx of junior officers to carry on the duties that are now being performed by those more senior in the service. The British Medical Association held out strongly for the removal of a serious grievance in regard to the retiring pension of an officer after twenty years' service, and it pointed out that it was possible in the future for a major to have to retire on a less pension than £1 a day,

<sup>1</sup> BRITISH MEDICAL JOURNAL, July 3rd, 1926, p. 41.

<sup>2</sup> Report of Annual Representative Meeting, Nottingham, 1926, BRITISH MEDICAL JOURNAL SUPPLEMENT, July 31st, 1926, p. 83.

which had been granted to him from time immemorial. The new Warrant relieves him of anxiety in this respect, and explicitly states that his pension cannot be reduced below that amount. Another important point should be noted—namely, the concession by which a newly qualified medical man can hold a hospital appointment for one year before entering the service, counting it as a year of service towards promotion and retirement. Previously this concession was only given after the officer had entered the service. This was one of the points that were strongly brought forward in the evidence submitted by the Association to the interdepartmental committee, and should give special satisfaction to members of the medical profession. It will be seen that both the Royal Navy and Royal Air Force Medical Services have also benefited considerably by the recommendations of the committee.

### ROYAL NAVAL MEDICAL SERVICE.

AN Admiralty Fleet Order, issued in July, 1926, announced changes in the terms and conditions of service for naval medical officers. The improvements include an increase in the establishment of Surgeon Captains from 16 to 20, and also in the number and remuneration of specialist appointments open to medical officers. These appointments comprise specialist posts in medicine, surgery, radiology, and hygiene, and the allowance payable to holders of them has been raised from 2s. 6d. to 5s. a day. As soon as possible courses of instruction in clinical medicine, surgery, and allied subjects are to be provided once in every four years for all officers below the rank of Surgeon Captain; courses for those selected to hold specialist appointments will be arranged in connexion with civil hospitals in London or other teaching centres. Medical officers entering the Navy on or after July 1st, 1926, will be eligible, at the discretion of the Admiralty, to have their seniority antedated up to a limit of one year if they have held previously a resident appointment in a civil hospital for not less than this period. Such an appointment must be one recognized by the Admiralty for this purpose, and must not have terminated more than six months before entry into the Service.

Examinations for direct entry into the Medical Service are at present in abeyance. Entries are made by means of the short-service scheme, and the regulations provide for the transfer to the permanent service of desirable short-service officers. A short-service surgeon lieutenant, after six months' service, may be considered for transfer to the permanent service, and would be permitted to count his seniority from the date of entry for short service for purposes of promotion, increment of full pay, and for retired pay.

#### General Conditions.

A candidate must be registered, must be under 30 years of age, and must be recommended by the dean of his school. Unmarried candidates will be preferred. A candidate will be interviewed by the Medical Director-General, R.N., and will undergo a physical examination. If considered eligible by the Medical Director-General his name will be submitted to the Board of Admiralty and he may be appointed "surgeon lieutenant for short service." A candidate must engage for three years, with the option of continuing for a further period of twelve months if his services are still required. The rate of pay is 25s. a day, or £456 5s. a year, with the same allowances as are payable to permanent officers of their rank. Lodging money at the rate of £80 a year is usually allowed when employed on shore, without quarters in the United Kingdom, and £56 10s. a year in lieu of rations when not victualled in kind. In cases of temporary employment on shore not exceeding thirty days, the lodging and provision allowances will be at the rate of 8s. and 3s. 6d. a day respectively. On joining an allowance of £53 for uniform will be made. When the previous rates of pay were fixed it was decided that 20 per cent. should be considered as due to the then high cost of living. The rates set out above represent a reduction of approximately 51 per cent. owing to the decrease in the cost of living. The whole 20 per cent. is to be regarded as variable and subject to change on July 1st, 1927, and triennially thereafter either upwards or downwards according as the cost of living rises or falls.

An officer engaged for three years is entitled to receive two months' notice of his services being no longer required. A gratuity of £3 6s. 8d. will be payable to officers for each completed month of service on completion of their period of service, or to any who are invalided for causes not within their own control before the completion of the prescribed period.

Surgeon lieutenants R.N. for short service intending to apply

for transfer to the permanent list must have been under 28 years of age at the time of their entry into the Royal Naval Medical Service.

Full particulars and a form of declaration can be obtained from the Medical Director-General, Admiralty, 68, Victoria Street, London, S.W.1.

### ARMY MEDICAL SERVICE.

DURING the last two years, and in fact since the war, candidates have practically ceased to apply for commissions in the Royal Army Medical Corps. While the cause of this must to a great extent be attributed to the war, a still more potent cause latterly has been an accumulation of grievances of a character which led the British Medical Association, in last year's Educational Number of the JOURNAL, to refrain from recommending the army as a career for newly qualified medical men. This attitude we are now able to abandon whole-heartedly owing to the issue of a Royal Warrant, on July 29th last, removing practically all the grievances from which the R.A.M.C. officers were suffering.

Competitive examinations for regular commission, which have been in abeyance for some time, will again be held half-yearly, in January and July. These examinations in medicine and surgery are entirely of a clinical and practical character, partly written and partly oral. The regulations for admission, giving full details, can be obtained from the Under Secretary of State (A.M.D.1), War Office, Whitehall, London, S.W.1, and should be carefully studied. A personal interview with a representative of the Director-General, Army Medical Services, is readily obtainable. The rates of pay and allowances are good; the opportunities of post-graduate study are generous; and the work is varied, responsible, and interesting. The gratuities after certain periods of service enable an officer, should he so desire, to leave the service with a capital sum large enough to go a long way towards re-establishing himself in civil life, and, further, the knowledge of the world and the comradeship of his fellow officers that he has gained in the army will be of no small value to him.

New entrants are commissioned in the rank of lieutenant, and the first six months of service are spent on probation, during which time they undergo, in addition to their military training at the Royal Army Medical Corps depot at Aldershot, a probationary course at the Royal Army Medical College in London in hygiene, pathology, tropical medicine, military surgery, recruiting, the prevention and treatment of venereal disease, and the elements of army administration. At the end of this course, and after qualifying at the necessary examinations, their commissions are confirmed and they take their places in seniority according to the total marks obtained at all examinations up to that date. Officers' Training Corps service with possession of certificate "A" or "B" (medical) carry a definite value in marks in this total.

An entrant who is holding or about to hold at the time of the entrance examination a resident house appointment at an approved civil hospital may be seconded while holding such an appointment up to a maximum period of twelve months. A candidate who has held such an appointment within six months of entry may be granted an antedate up to twelve months in respect of the period the appointment was held. This secondment and antedate counts in all respects as commissioned service, except that pay will not be issued for that period.

After a total period of one year's service at home, the young officer goes abroad, probably to India, for his first tour of foreign service. Here he gains his first practical experience of tropical disease and tropical hygiene, and possibly his first experience of active service on the frontiers of India. His tour abroad lasts five years, with probably six months' leave home during that time. On returning home the R.A.M.C. officer has the opportunity to decide whether he will remain in the corps or accept the gratuity of £1,000 after seven years' service and try his fortune in civil life. If he elects to remain, he will, between his eighth and twelfth year of service, undergo a course of post-graduate study at the Royal Army Medical College and the London hospital; of five months' duration, followed by a course of study of a special subject selected by himself provided he has shown special aptitude in the post-graduate course or during his previous service. During this period of study he remains on full pay and the fees of the courses are paid by the State. When qualified in his special subject the officer becomes entitled to specialist pay at 5s. a day when holding a specialist appointment. After this post-graduate course the officer probably proceeds abroad again and promotion to major rapidly ensues, and from that time onward the officer receives regular successive increases of pay and is eligible for additional and charge pay as well. The directorates of hygiene and pathology and the appointment of two serving officers as consultants in medicine and surgery have been instituted, and have proved a marked success. All these appointments are of the rank of colonel or major-general, and were devised to permit specially

\* Pay Warrant rates as amended by Army Order 195/26, less 5½ per cent. from July 1st, 1924 (vide Army Orders 93 and 204 of 1924). The Pay Warrant rates are subject to revision to an extent not exceeding 20 per cent., according to variation in the cost of living. The next revision takes place from July 1st, 1927.

† Rates of Allowances vary from time to time, and issues are subject to conditions laid down in the Allowance Regulations.

selected officers to rise through all ranks to that of major-general on the strength of their professional or purely scientific work. This side of the work of Royal Army Medical Corps officers is carefully watched by these directors and consultants, and not only ensures the maintenance of a high standard but enables the good professional work of individuals to be brought to notice.

Under these conditions the possibilities for good workers are very great in the Royal Army Medical Corps. There is scope for original research in tropical disease, in preventive medicine, and in bacteriology, as well as in the large clinical field open to the specialist in medicine, surgery, or gynaecology, in venereal disease, and in ophthalmology. Child welfare is also undertaken systematically by officers of the Royal Army Medical Corps. At the same time, instruction in administration is continuous. The Royal Army Medical Corps is essentially organized for war, and one of the lessons of the great war was that trained administrators must exist to enable the fullest benefit to be obtained from professional talent. Many appointments carrying administrative responsibility are open to those officers who display capacity for this duty. All officers must be prepared to undertake command and to have a knowledge of army administration, especially in war. Equally important is the technical training of the non-commissioned officers and men of the corps in such "trades" as trained nurse, nursing orderly, masseur, radiographer, operating room assistant, laboratory assistant, hospital cook, dispenser, etc. This training is carried out by the officers and nursing sisters, and opens a large field for those who have ability in lecturing and teaching as well as the power of influencing men.

#### Promotion.

Promotion takes place automatically to captain after three and a half years' and to major after twelve years' service, provided the officer is qualified and recommended for promotion. Promotion to the higher ranks is by selection from those senior in the rank below, but special promotion by brevet or otherwise is open to officers of the Royal Army Medical Corps.

#### Pay and Allowances.

The rates of pay and allowances are given in the accompanying Table A; they compare favourably with those that obtained before the late war.

#### Additional Pay and Charge Pay for Officers of the R.A.M.C.

An officer not above the rank of lieutenant-colonel while acting as a specialist receives up to 5s. a day according to subject or group of subjects. An officer in charge of a hospital receives charge pay, the daily amounts being: in excess of 50 beds, 2s. 6d.; in excess of 150 beds, 5s.; in excess of 300 beds, 7s. 6d.; in excess

of 500 beds, 10s. An officer in charge of a medical or surgical division of a general hospital with not less than 300 beds receives half these rates. Senior medical officer Royal Arsenal, not exceeding 10s. daily. Officer in command of the depot R.A.M.C., 5s. daily. The senior officer of the Army Medical Services with an army in the field, a rate to be fixed by the Army Council according to the magnitude of the charge. The officer, if under the substantive rank of colonel, holding the appointment of senior medical officer in a command abroad, or of assistant director of medical services, if the number of soldiers is 1,500 or upwards, 5s. daily. Adjutant R.A.M.C. depot, 5s. daily. Adjutant R.A.M.C. (T.A.), 2s. 6d. Further, an officer, graded as a specialist, and appointed to the charge of a medical or surgical division of a general hospital, may be allowed to retain his additional pay and to draw the rate of charge pay laid down for the officer in charge of a medical or surgical division of a general hospital, provided that the total of additional and charge pay so drawn does not exceed the rate of charge pay drawn by the officer in charge of the hospital. With this exception charge pay and additional pay as specialist will not be issuable concurrently.

#### Retirement and Retired Pay.

Retired pay will consist of two parts: (a) a service element based on the officer's total service; (b) a rank element for the rank from which the officer retires. An officer with less than twenty complete years' service will not be eligible for retired pay. The scale, subject to the reduction of 5½ per cent. referred to below, is, for the service element, £15 a year for each completed year of service as a medical officer. For the rank element the scale is as follows:

| Rank from which Retired.  | After Completing 1 Year's Service in the Rank. | After Completing each Additional Year's Service. | Maximum Rank. |
|---------------------------|--|--|---------------|
| Major ... ..              | £<br>12  | £<br>12  | £<br>L.O      |
| Lieutenant-Colonel ... .. | 153  | 30   | 243           |
| Colonel ... ..            | 290  | 50   | 390           |
| Major-General ... ..      | 440  | 50   | 540           |
| Lieutenant-General ... .. | 590  | 50   | 690           |

The retired pay of an officer retiring with less than one complete year's service in the rank from which he retires will be assessed as though he had retired from the rank below.

The maximum rates of retired pay are as follows:

|                              |        |
|------------------------------|--------|
| Captain and Subaltern ... .. | £300   |
| Major ... ..                 | 1,250  |
| Lieutenant-Colonel ... ..    | 1,650  |
| Colonel ... ..               | 1,950  |
| Major-General ... ..         | 11,000 |
| Lieutenant-General ... ..    | 11,200 |

The above rates are those laid down in the Pay Warrant. They have been reduced by 5½ per cent. as from July 1st, 1924.

Officers with seven and less than twenty years' service as

## Royal Air Force Medical Service: Rates of Pay and Allowances.

| Rank.                                | Pay.*            |                  |                           | Cash Allowances in lieu of Quarters, Rations, and Servant, if not available in kind (per annum).† |                     | Pay plus Allowances (per annum). |                     |

\* Except for periods of service under Indian administration. For such periods officers receive pay and allowances at rates and subject to conditions authorized from time to time by the Government of India.

† These allowances are issued provisionally in kind is available for a colonial allowance is granted. and light, rations and personal attendance are not available in kind. Normally, allowances are payable only to married officers who have reached the age of 31.

The rates and general scheme of allowances are liable to revision as circumstances may require.

which the appointment is held. If the applicant already holds the appointment when the commission is granted, the commission may be antedated to the date on which the appointment was first held, provided (a) that the appointment is held for not less than one year, (b) that the period of secondment and the period of antedate shall not together exceed one year, and (c) that the antedate shall not be made until the officer has joined for actual R.A.F. duty.

(2) An officer granted a short-service commission on or after July 1st, 1926, who has previously held a resident appointment in a recognized civil hospital for a period not less than one year may, provided the commission is granted not more than six months after the termination of the hospital appointment, be granted an antedate of the commission equal to the period of the appointment up to a maximum of one year.

(3) The term "resident appointment" as used at (1) and (2) may be held to include a period of not more than six months in a non-resident appointment immediately preceding or following a resident appointment.

(4) If necessary, the ordinary maximum age for appointment to a commission may be increased by a period equal to any antedate granted under (1) and (2).

(5) An officer who has been seconded or whose commission has been antedated as above will be required to serve for a minimum period of three years on the active list from the date of joining for actual R.A.F. duty.

(6) Pay and allowances for periods of secondment or antedate will not be allowable, and such periods will not be reckoned in the assessment of gratuities payable to short-service officers. Subject to (5), however, such periods will be reckoned as commissioned service in the Royal Air Force for purposes of seniority and promotion, and, in the case of permanent officers, of retirement, retired pay, and retirement gratuities.

Officers who have been selected for permanent commissions may be permitted to attend for a period not exceeding nine months a post-graduate course in general medicine and surgery, tropical and preventive medicine, and other special subjects. Such permission may be granted at any time when the exigencies of the service permit during the first sixteen years of service, and when attending these courses officers will receive full pay and allowances.

New entrants into the R.A.F.M.S. will be commissioned as Flying Officers (Medical), and will be eligible for promotion to the rank of Flight Lieutenant (Medical) after two years' service. Officers selected for permanent commissions will normally be promoted to the rank of Squadron Leader after ten years' total service. Accelerated promotion may be granted in a limited number of cases to officers who show exceptional ability after the completion of eight years' service. Promotion within establishment to the rank of Wing Commander will be by selection at any period after sixteen years' total service, and to that of Group Captain by selection at any period after twenty-two years' service.

There will be no competitive examination on entry; candidates must be under 28 years of age, be British subjects, the sons of British subjects, and of pure European descent, be nominated by the dean of a recognized medical school or teaching hospital, and will be interviewed personally by the Director of Medical Services, Royal Air Force, before acceptance. Each candidate must produce:

1. Birth certificate.
2. Medical registration certificate.
3. A declaration containing the following information: (a) Age, and place of birth. (b) That he is a British subject, the son of British subjects, and of pure European descent. (c) That he is ready to engage for general service at home or abroad as required. (d) The qualifications he is possessed of and what medical or other appointments he has held (if any). (e) That he is willing to fly as a passenger whenever called upon to do so.

Each candidate will be required, before acceptance, to pass a medical examination to ensure that he labours under no constitutional or mental disease or diseases or weakness, nor any imperfection or disability which may interfere with the efficient discharge of the duties of a medical officer in any climate, in peace or war.

On appointment entrants will undergo an initial course of eight weeks, during which they will be given instruction in the special medical aspects of aviation; the organization and administration of the Royal Air Force; and the general and special duties to be performed by officers in the Medical Branch. In order to avoid the necessity for further examinations the position of entrants in order of seniority in the Air Force List will be determined at the end of the initial course by a system of marking and reports on the actual work done during their instruction.

## Uniform and Equipment.

Medical officers are required to provide themselves with the uniform, service dress, and mess dress of their rank, and with the distinguishing badges of the Royal Air Force Medical Branch. The provision of full dress is entirely optional at present. An allowance of £50 towards the cost of uniform is made on joining to candidates who have not had previous commissioned service in H.M. Forces.

## Pay and Allowances.

The emoluments of medical officers of the Royal Air Force are given in outline below. The standard rates of pay and retired pay were drawn up on the basis of the high cost of living in 1919, and 20 per cent. of each of the standard rates is detachable and subject to alteration, either upwards or downwards, as the cost of living rises or falls. Under this

provision the current rates now in force represent a reduction of approximately 5½ per cent. on the standard rates. The next revision will take effect from July 1st, 1927, and subsequent revisions will be made at intervals of three years.

#### Retired Pay.

The minimum period of service qualifying for retirement on retired pay is twenty years. Standard rates of retired pay are as follows:

*Air Officers.*—Air Vice-Marshal, £790 to £1,010 per annum; Air Commodore, £650 to £950 per annum.

#### Officers Below Air Rank.

| Age on Retirement. | Yearly Rate of Retired Pay. | Years of Service. | Addition for each Extra Year of Service.* | Deduction for each Deficient Year of Service.* |
|--------------------|-----------------------------|-------------------|---|--|
|                    | £                           |                   | £   | £  |
| 40                 | 300                         | 17                | 15  | 15   |
| 41                 | 337                         | 17                | 15  | 15   |
| 42                 | 375                         | 18                | 15  | 15   |
| 43                 | 412                         | 18                | 15  | 15   |
| 44                 | 450                         | 19                | 15  | 15   |
| 45                 | 487                         | 19                | 15  | 15   |
| 46                 | 525                         | 20                | 15  | 15   |
| 47                 | 562                         | 20                | 15  | 15   |
| 48                 | 600                         | 21                | 15  | 15   |
| 49                 | 637                         | 21                | 15  | 15   |
| 50                 | 675                         | 22                | 15  | 15   |
| 51                 | 697                         | 22                | 22  | 15   |
| 52                 | 720                         | 23                | 22  | 15   |
| 53                 | 742                         | 23                | 22  | 15   |
| 54                 | 765                         | 24                | 22  | 15   |
| 55                 | 790                         | 24                | 22  | 15   |

\* Limited to five years.

The maximum standard rates of retired pay and the compulsory retiring ages for the several ranks are:

| Rank.                   | Yearly Rate of Retired Pay. | Compulsory Retiring Age. |
|-------------------------|-----------------------------|--------------------------|
|                         | £                           |                          |
| Air Vice-Marshal ... .. | 1,010                       | 60                       |
| Air Commodore ... ..    | 950                         | 57                       |
| Group Captain ... ..    | 900                         | 55                       |
| Wing Commander ... ..   | 600                         | 51                       |
| Squadron Leader ... ..  | 500                         | 48                       |

#### Gratuities.

A permanent officer allowed to retire before having qualified for retired pay may be granted a gratuity provided he has not less than ten years' commissioned service—namely, £1,500 if he has ten but not less than fifteen years' commissioned service; £2,500 after fifteen or more than fifteen years'.

Short-service officers will be eligible on passing to the Reserve for gratuities on the following scale: £160 for each of the first two complete years of service, £150 for each of the third and fourth complete years, and £200 for the fifth complete year; that is, for three years' service on the active list £350; for five years' £700.

These gratuities will not be payable to officers granted permanent commissions, but their service on a short-service commission will count towards retired pay.

#### INDIAN MEDICAL SERVICE.

As is known from the ordinary sources of information, British rule in India is going through a long period of crisis. The future of all the British services in India is uncertain, and that of the Indian Medical Service not least so. Medical and sanitary subjects were among those specifically mentioned as suitable for transfer to provincial Governments in the Montagu-Chelmsford report, which, it may be recalled, was issued over seven years ago. This

transfer was effected by the Government of India Act (1919). The Lee Commission, which visited India to inquire into the prospects and remuneration of the European services, made certain recommendations with regard to the Indian Medical Service in its report issued in May, 1924. They have been considered both by the Government of India and by the Secretary of State for India, but it appears abundantly clear that they will not be accepted by either.

In his speech opening the new session of the Indian Legislature at Simla in August, 1925, the then Viceroy, Lord Reading, said that the Government was now taking steps to give effect to the principle laid down by the Joint Select Committee of Parliament that a Minister should have the fullest opportunity of managing that field of government which was entrusted to his care. After stating that recruitment by the Secretary of State for the Indian Educational, Agricultural, and Veterinary services had already ceased, he said that the problem presented by the Indian Medical Service was more difficult, but there, too, the principle of establishing provincial medical services had been accepted, subject to certain conditions, which were still under consideration. This statement leaves many essential points unexplained, and it is to be presumed that publication of the official proposals in their entirety will not be much longer delayed. When issued they will be examined by the Naval and Military Committee of the British Medical Association, and the decision of the Council of the Association on the advice it gives will be published in due course.

Since the open competitive examination held in July, 1915, for admission to the Indian Medical Service no similar examination has been held, but such appointments as were required to meet the indispensable needs of the Service have been made by nomination by the Secretary of State for India. In view of the present abnormal conditions it is announced that this method of recruitment will continue to be in force until further notice. To assist him in making appointments, the Secretary of State has appointed a Selection Committee, who will summon and interview such applicants as may appear to be *prima facie* suitable, and make recommendations for appointment. A similar Committee has been appointed in India to investigate applications and to forward recommendations to the Secretary of State.

#### Special Recruitment.

In a circular dated July, 1926, the Secretary of State announced his intention of appointing a certain small number of medical men of European descent in the near future to permanent commissions in the Indian Medical Service, on the special terms set out below. Candidates must be well qualified medical practitioners over 21 and under 32 years of age. Appointment will be by nomination on the recommendation of a Selection Committee, before whom candidates will have to appear in person. The special terms are as follows:

(a) On completing either six or twelve years' active service in India, an officer so appointed may claim to retire on a gratuity of £1,000 or £2,500 respectively, provided that he has given notice of his intention twelve months in advance. If he does not do so, he will continue in the service on the ordinary pensionable footing. If an officer applies and is permitted to retire at any time between the completion of his sixth and twelfth years of service, or between the completion of his twelfth and seventeenth years of service, he will be eligible for a gratuity of £1,000 only, or £2,500 only respectively. In addition to actual service only privilege leave (that is, leave on full pay for sixty days in each year) will be allowed to count towards the period of six or twelve years required for the gratuity, and not ordinary furlough or sick leave.

(b) Officers so appointed will be eligible for the passage concessions set forth in the accompanying Provisional Regulations, except that no concession passage will be granted before the completion of five years' service, and then only if the officer has not given notice to retire in accordance with the preceding sub-paragraph. Otherwise he will be provided with a free passage for himself and his family to the United Kingdom or to any port in the British Empire to which he may wish to proceed, on the completion of six years' service. Similarly, on the completion of eleven years' service an officer will become eligible for a second concession passage if he has not given notice as above, or he will receive free passages to the United Kingdom or any port in the British Empire if he retires on completion of twelve years' service. Passages granted on retirement must be claimed within three months of the date of retirement. An officer invalided home on sick

leave during his first twelve years of service will be granted a free passage, but any such passages granted to him will count against any concession passage or passages to which he may be entitled. But if he retires otherwise than on account of ill-health before becoming entitled to benefits under the passage rules, he will be required to refund the cost of the passages granted for sick leave.

In view of the reorganization of the Indian Medical Service which is now under consideration, only military employment can be guaranteed to officers entering the I.M.S. at the present time. They will, however, be eligible for the benefits of any conditions regarding civil employment which may be made applicable to officers in future appointed to the I.M.S. as the result of decisions taken on the Lee Commission Report.

In all other respects the ordinary rules and conditions, as set forth in Regulations for the Appointment of Candidates to Commissions in the I.M.S., will apply. Officers retiring on a gratuity after twelve years' service will be liable, equally with those retiring on pension, to recall to military duty in case of emergency up to 55 years of age. They would only be recalled to duty in the event of an emergency which exhausts the capacity of the reserves permanently maintained in civil employ in India.

The officers appointed will sail for India in the autumn of this year. It is hoped to arrange for them to attend a course of instruction before doing so.

Application forms and any further particulars desired may be obtained from the Secretary, Military Department, India Office, Whitehall, S.W.1. Envelopes should be marked "Medical Recruitment."

### PRISON MEDICAL SERVICE.

CANDIDATES for the medical staff are approved by the Secretary of State for the Home Office on the recommendation of the Prison Commissioners. The Chairman of the Board is Mr. M. L. Waller, C.B. Application for employment may be made to the Board on a special form, which can be obtained from the Secretary, Prison Commission, Home Office, London, S.W.1.

In the smaller prisons the medical officer is usually a local practitioner, but in the larger the members of the medical staff are required to devote their whole time to the service. In the case of those required to give their whole time to the service the appointment in the first instance is to the post of medical officer Class II, and from the seniors of this rank the medical officers Class I are selected as vacancies occur.

In February, 1923, the then Home Secretary appointed a committee to report on what changes, if any, should be made in the remuneration or other conditions of service of officers at the prisons and Borstal institutions in England and Scotland and at Broadmoor Criminal Lunatic Asylum. Evidence was given on behalf of the British Medical Association by the Medical Secretary, who pointed out that the salary offered to Class II medical officers—namely, a basic salary of £300 rising by annual increments—was, even when the allowances and bonus were reckoned in, less than the £500 a year the Association looked upon as the minimum commencing salary which should be given to a whole-time medical man holding such a responsible office. The committee issued its report in November, 1923. It recommended that officers of both classes should receive an additional £50 a year, and from a communication received from the Prison Commission we understand that the pay of the whole-time prison medical staff is: Medical officer Class II, £350, rising by annual increments of £20 to £600; medical officer Class I, £650, rising by annual increments of £25 to £800. Unfurnished quarters are provided, or an allowance in lieu is made. The civil service bonus is paid on the salary. There are 15 medical officers Class II, 12 medical officers Class I, and 23 part-time medical officers.

The number of vacancies is never large, and promotion is slow.

### MEDICAL PRACTICE IN BRITISH DOMINIONS AND FOREIGN COUNTRIES.

MEDICAL Acts have now been passed in almost all places forming part of the British Empire beyond the seas, and registers of duly qualified practitioners are consequently maintained. To these registers medical men educated in

the United Kingdom are always admissible merely on payment of a registration fee, providing they produce evidence that they are of good repute and are either registered or eligible for registration in the United Kingdom, as the local requirement may be. The only exception to this statement that need be made relates to the Dominion of Canada. Each of its provinces acts in medical matters as an independent State. The result has been that reciprocity of practice has in the past been established between this country and all the provinces of Canada except British Columbia, where certain obstacles still remain to be overcome. It has, however, to be recorded that reciprocity with Saskatchewan has recently been brought to an end by that province, and the arrangement with New Brunswick is also likely to be ended shortly owing to their action. We would advise any medical man proposing to practise in Canada first to communicate with the Provincial Registrar, stating what degrees or diplomas he holds, and asking for information as to the precise steps he must take in order to obtain admission to the Provincial Register.

Italy and Japan are the only two foreign States with which complete medical reciprocity has been established, though there are other countries which grant a limited recognition to British qualifications. Generally speaking, in Continental countries (with the exception of the kingdom of Italy) a British medical man desiring to exercise his profession therein must pass practically the same examinations as those imposed on natives of the country. The same observation applies to all foreign States in the South American continent. Each of the United States of North America has its own laws and regulations governing medical practice; and all of them require the holder of a British qualification to submit to an examination. The States of New York and Indiana require an applicant to be naturalized.

A pamphlet showing the conditions under which medical and dental practitioners legally qualified in their own country may practise abroad can be obtained from the office of the General Medical Council, 44, Hallam Street, Portland Place, London, W.1, price 2s. 6d., or 2s. 9d. post free in the United Kingdom. Practitioners who think of going abroad to practise will find therein much useful information, including the name of the official in each country to whom requests for further particulars should be addressed. The last edition was published in January, 1921, and a new one is now in course of preparation.

### MEDICAL APPOINTMENTS IN THE COLONIES AND MANDATED TERRITORIES.

MEDICAL appointments in the self-governing Dominions and the territories under their control, and in Southern Rhodesia, are made by the Governments concerned, and are not in general open to candidates in the United Kingdom. Appointments to the medical services of the colonies and other territories under the administrative direction of the Colonial Office are, apart from those in Ceylon, Mauritius, Jamaica, Barbados, the Bahamas, Bermuda, and Malta, which are filled locally, made by the Secretary of State for the Colonies in this country. Such appointments are to a given colony or colonies, for there is no unified service directly administered from the Colonial Office. It follows that conditions of service and superannuation are in the main determined by the economic resources and general public health policy of the individual colony and its local Government, and vary almost as widely as do conditions of climate. Moreover, the extent of the control exercised by the Colonial Office varies according to the constitutional status of the particular colony, and the detailed information available centrally is not always either up to date or complete. The intending candidate, therefore, should make comprehensive inquiries as to local conditions, and particularly as to facilities for private practice where this is included in the terms of appointment. He will also do well to supplement official information by reference to the central office of the British Medical Association, where reports obtained from time to time from the local Branches are available. This is the more necessary because facilities

for transfer from the Medical Service of one colony to that of another are as yet practically non-existent, except in connexion with a few specialist and senior appointments; this sets strict limits upon the opportunities for promotion.

To those physically and mentally suited for the climatic and social conditions peculiar to the various colonies the Colonial Medical Services should, and in some cases do, offer a field of professional activity rich in interest and in opportunity for pioneer work. The scope for research is wide, and facilities for its prosecution are beginning, however tardily, to be provided. An increasing number of specialist posts is becoming available in the larger services, and the general policy is to fill them by promotion of suitably qualified junior officers. The potentialities of sanitation are beginning to be appreciated by local administrations, however vaguely. But, when all is said, it cannot be contended that conditions in the Colonial Medical Services are generally satisfactory. In some instances, indeed, they can only be characterized as intolerable. Hence the necessity for very full inquiry before accepting appointment. It is true that the post-war economic stringency to which the delay of essential reform was usually attributed is giving place to more favourable conditions. There are also signs of increasing parliamentary and departmental interest in the development of a sound health policy. The long-delayed appointment of a medical adviser to the Secretary of State for the Colonies should do much to promote the creation of conditions which will permit the medical services to give full effect to such a policy. Meanwhile, those services are too often hampered by conditions which make efficiency unattainable. At the worst they are in some colonies starved of material resources in the name of economy, understaffed, and underpaid, with inadequate facilities for study leave, and at the mercy of an administration in which the nominal head of the service has no effective voice. Hence the urgent necessity for making careful and sufficient inquiry as to the position in any given service before appointment is accepted.

The medical services recruited in this country by the Secretary of State for the Colonies include those of West Africa, East Africa, Malaya, Hong-Kong, the West Indies, Fiji and the Western Pacific Colonies, and Palestine, besides a number of small services offering individually one or two appointments at an inadequate remuneration and with no prospects of promotion. The services in the West Indies, and in Fiji and some of the smaller colonies, have not yet conceded the £600 minimum commencing salary recommended as adequate by the British Medical Association, and whilst facilities for remunerative private practice, general conditions of service, and a relatively low cost of living must in some instances be taken into consideration, these compensations are by no means universal. The services in the Leeward and Windward Islands are in a condition which requires special notice by way of warning.

In general, candidates for these services must be between the ages of 23 and 35, although these limits are not for the moment absolute. A candidate over 35 years of age, if accepted for appointment, may be required to serve on a temporary and non-pensionable footing; regular appointments are, subject to a varying period of probation, for the most part classed as permanent and pensionable. There is no entrance examination, but practitioners selected for appointment must obtain a certificate of physical fitness from one of the Medical Advisers of the Colonial Office. Post-graduate experience in hospital appointments is desirable, and in some cases special allowances are conceded to the holders of a D.P.H. or other additional qualifications. Successful candidates for the West African Medical Staff, the East African Medical Service, and the Malayan Services are, in general, required to undergo an approved course of instruction in tropical medicine. The cost of this, subject to a minimum period of service being performed, is met by the Colonial administrations.

The bulk of the appointments made by the Secretary of State in this country are to the West African Medical Staff, the East African Medical Service, and the Medical Services in Malaya. These are the strongest individual services numerically, and therefore offer more frequent

vacancies, better prospects of promotion, and better chances of specialist appointments than the smaller services.

#### WEST AFRICAN MEDICAL STAFF.

This is amongst the best organized and best paid of the Colonial Services, though at present it appears to be understaffed. The territories covered by the service include Nigeria, the Gold Coast, Sierra Leone, and the Gambia. Climatic conditions vary considerably over this area, but they are in general admittedly trying. This fact is at present recognized by the provision of more frequent leave periods than are usual elsewhere. The growing opinion that conditions are less adverse than they have been in the past is marked by the proposal to extend the tours of service. The rate of pay for a medical officer of £660 on appointment, rising by annual increments to £956. There are, in addition, certain seniority and duty allowances, and there are a number of specialist and administrative posts carrying relatively high salaries. The pension after 18 years' service is £570. Gratuities of £1,000 or £1,250 may be drawn on retirement after 9 or 12 years' service. Members of the West African Medical Staff are not permitted to take their wives or young children to the West Coast until they have acquired experience of the conditions of life and have obtained the sanction of the Governor. In the case of young children this is only exceptionally given.

#### EAST AFRICAN MEDICAL SERVICE.

This service includes Kenya, Uganda, Tanganyika Territory, Nyasaland, Zanzibar, and British Somaliland. In East Africa there is very wide scope for clinical work both medical and surgical, as well as for research and for preventive medicine and sanitation. The Service as a whole is fully alive to its responsibilities and opportunities; individual initiative is encouraged, and the career of a medical officer depends, not on seniority alone, but to a large extent on his own capability. As a rule it is preferable that medical officers on first appointment should not be married, although in all but a few stations conditions allow a medical officer's wife to accompany him. The Service includes a medical and a sanitary division.

#### Scale of Salaries.

| Post.   | Old Salary.   | Revised Salary   |
|---|---|--|
| Director of Medical and Sanitary Services (Kenya)                                   | £1200   | £1500  |
| Director of Medical and Sanitary Services (Uganda)                                  | £1200   | £1500  |
| Director of Medical and Sanitary Services (Tanganyika)                              | £1200   | £1500  |
| Director of Medical and Sanitary Services (Zanzibar)                                | £1000   | £1400  |
| Director of Medical and Sanitary Services (Nyasaland)                               | £1000   | £1200  |
| Deputy Directors (Kenya, Uganda, Tanganyika)  | £1000   | £1200  |
| Deputy Director of Sanitary Service (Zanzibar) (formerly Senior Sanitation Officer) | £800-£900+£100  | £1200  |
| Directors of Laboratory (Kenya, Uganda, Tanganyika)                                 | £900-£1000  | £1200  |
| Resident Surgical Officer (Uganda) ...  | £900-£1000  | £1150  |
| Sleeping Sickness Officer (Uganda) ...  | £900-£1000  | £1150  |
| Medical Superintendent (Mulago, Uganda)   | £900-£1000  | £1150  |
| Principal Medical Officer (Somaliland) ...  | £900-£1000  | £1000-£950-£1100   |
| Senior Medical Officers... ..   |   |  |
| Senior Sanitation Officers ... ..   |   |  |
| Resident Surgical Officer (Zanzibar) ...  |   |  |
| Senior Bacteriologists (Kenya and Uganda)   | £300-£25-£900   | £1000-£950-£1100   |
| Medical Entomologist (Nyasaland) ...  |   |  |
| Sleeping Sickness Officer (Tanganyika) ...  |   |  |
| Venereal Diseases Officer (Tanganyika) ...  |   |  |
| Medical Officers ... ..   | £500 by £25 to £900, with efficiency bars at £700 and £800. | £500 by £30 to £840, and by £40 to £920 with efficiency bar at £840. |
| Sanitation Officers ... ..  |   |  |

Note.—Medical officers actually serving in Kenya, Uganda, and Tanganyika at date of introduction of scheme have right to proceed by further increments of £10 to £1000, subject to an efficiency bar at £920.

The former is open to those holding ordinary medical and surgical qualifications, post-graduate experience in a hospital appointment being an advantage; posts in the sanitary division will as far as possible be filled by those holding a Diploma in Public Health. Climatic conditions vary considerably. In the greater part of Kenya they approximate more to the temperate than the tropical zone; but there are some areas in the East African Dependencies where conditions more closely resemble those in West Africa.

Whilst a candidate can only apply for appointment to the East African Medical Service in general and is liable to transfer between the several dependencies, he may express his preference for any particular colony and his wishes will, we are informed, be met as far as possible. As a rule transfer only takes place on promotion or at an officer's own request. The gratuities available on retirement after 9 or 12 years' service are similar to those for the West African Medical Staff. Pensions are calculated at the rate of 1/60th of retiring salary, plus 15 per cent. of the initial salary of the grade, for every year of service.

It will be recalled that the Association has for some time past been urging the Secretary of State to improve the salaries of this and other branches of the Colonial Medical Service. We are now pleased to be able to publish in full the scale of salaries now in force (see page 462), those for Kenya, Uganda, and Zanzibar dating from January 1st, 1926, and those for Nyasaland and Tanganyika from April 1st, 1926. All local allowances have been abolished.

#### MEDICAL SERVICES IN MALAYA.

These services cover the Straits Settlements, the Federated Malay States, and some of the unfederated States. Unfortunately, the information in our possession shows a position so far from satisfactory that it is impossible for the moment to recommend the services to the consideration of the profession. Proposals for drastic reform are, however, under consideration, and further information as to the services will be published if and when the adoption of an adequate scheme can be announced. Meanwhile, it is satisfactory to be able to state that a letter has been received by the Association from the Colonial Office stating that it has been decided to raise the commencing salary of medical officers to 500 dollars a month.

#### SUDAN MEDICAL SERVICE.

This service is a department of the Sudan Government, and includes a number of Syrian medical officers and a number of assistant medical officers who are natives of the Sudan. The British medical inspectors are from the outset senior to all other medical officers. The Sudan is entering on a period of rapid development and expansion, to which the medical services of the country must necessarily make an important contribution. The service offers ample opportunities for specialization and for research, as well as for general medical and surgical work. The ordinary duties of a medical inspector may be summarized as follows:

- (1) To act as a consulting surgeon and obstetrician in all cases submitted to him by his medical staff. This necessitates considerable surgical experience.
- (2) To initiate, organize, and supervise all medical and sanitary work in his province. This includes extensive antimalarial work and often the supervision of large irrigated areas.
- (3) To carry out the medical supervision of schools and the examination of candidates for Government service and pension.
- (4) To train assistant medical officers and native sanitary overseers, and to advise and direct medical officers in the carrying out of their duties.
- (5) Probably, at a later date, to take part in teaching at the School of Medicine at Khartoum.

The climate varies, but is not in general unfavourable, though hot. In the northern desert the nights are cool, even in the summer; in the central there is a rainy season of about four months, during which large areas become malarious. The southern area is more tropical in character, and mosquito-protected houses, nets, and protective quinine are essential during the greater part of the year, though

the winter months are cool and pleasant. It is not considered desirable for medical inspectors to be accompanied by their wives until they have gained some knowledge of the language and the general conditions of life.

The commencing pay of a medical inspector is £E.720.\* On confirmation of appointment and success in the requisite examinations in Arabic the salary is increased by periodic increments to £E.1,200. There are four senior administrative posts carrying higher salaries. There is a compulsory contribution of 5 per cent. of pay towards pension, which, for a medical inspector, amounts, after twenty years' service, to £E.500 a year.

#### PALESTINE.

A few of the senior posts in the Health Department of the Government of Palestine are recruited in this country. The scales of pay vary between £E.550-25-750 for an assistant principal medical officer and £E.1,100-50-1,400 for the director.

#### OFFICIAL SOURCES OF INFORMATION.

All inquiries in connexion with medical appointments in the self-governing Dominions and their dependencies should be addressed to the High Commissioners or Agents-General for the Dominions. Intending applicants are also recommended to consult the Colonial Office List, which may be seen at the Colonial Office Library or at the central office of the British Medical Association if not otherwise available, and the Professional Handbook (price 6d.) issued by the Overseas Settlement Office, 3 and 4, Clement's Inn, Strand, London, W.C.2.

Recent developments seem to suggest the possibility of a few appointments becoming available under the Egyptian Government. Questions about any such appointments should be addressed to the Director-General, Public Health Department, Cairo.

Inquiries as to vacancies and conditions in the Sudan Medical Service should be addressed in the first instance to Dr. T. D. Acland, 19, Bryanston Square, W.1.

All inquiries in connexion with Colonial medical appointments made by the Secretary of State for the Colonies, or such vacancies as may occur in Iraq, Palestine, or Aden, should be addressed to the Assistant Private Secretary (Appointments), Colonial Office, Downing Street, London, S.W.1.

There remain a number of medical appointments made by mining companies and other commercial undertakings in various parts of the tropics. Much caution should be exercised in accepting such posts, and the form of contract should be subjected to very careful scrutiny. Advice in this connexion should always be sought from the Medical Secretary's Department of the British Medical Association, British Medical Association House, Tavistock Square, W.C.1.

## MEDICAL RADIOLOGY AND ELECTROLOGY.

### THE CAMBRIDGE DIPLOMA.

A DIPLOMA in Medical Radiology and Electrology is granted by the University of Cambridge. The primary object is to provide adequate training in a branch of medical work which is becoming increasingly important and difficult, and which is outside the ordinary medical curriculum. The diploma is open only to those who hold a medical qualification, and includes a course of lectures and practical work in Physics (Part I) and in Radiology and Electrology (Part II). Attendance at the necessary courses of lectures in both subjects, and in addition six months' clinical experience in an adequately equipped hospital recognized by the Diploma Committee, is essential. The whole course of study takes six months, the lectures, practical work, and hospital attendance running concurrently.

The courses carried out by the University of Cambridge are at present arranged to begin early in January. Three months are spent at Cambridge doing the lectures and practical work in Part I, and attending the systematic lectures in Part II and the practice of Addenbrooke's Hospital, where there is a fully equipped and up-to-date

\* £E. = £1 0s. 6d. sterling. This figure represents exchange value, not purchasing power.

x-ray and electrological department. The remaining three months can be completed at any hospital recognized by the Diploma Committee for this purpose, a list of which can be obtained, but special arrangements are made for students to continue their studies in London, where demonstrations at various hospitals are arranged, in order to give a wide experience.

In addition, an independent six months' course is arranged by the British Institute of Radiology. This course is held entirely in London, but is recognized by the University as qualifying for the examination; it begins early in October.

Further particulars as to the Cambridge courses can be obtained from F. Shillington Scales, M.A., M.D., Medical Schools, Cambridge, and of the London courses from Stanley Melville, M.D., at the Offices of the British Institute of Radiology, 32, Welbeck Street, London, W.1.

### MEDICAL MISSIONARIES.

MISSIONARY societies are in constant need of qualified men and women to fill vacancies as they occur in their hospitals, and also to enable them to take advantage of fresh openings. To those suitably endowed the mission field offers unique opportunities for interesting work, and the development of native medical schools, as training institutions in connexion with some of the larger mission hospitals, affords excellent scope for valuable work to medical men and women who are qualified to teach. It is not usually expected that medical missionaries should take a position such as would otherwise be occupied by an ordained clergyman or minister, but it is essential that they should be prepared to exert their influence in any hospital to which they may be sent so that a Christian atmosphere may be maintained and the work of evangelization be carried on through the ministry of healing.

As for scientific and other qualifications for the work, medical missionaries, in addition to being physically capable of sustaining a life which makes a great demand upon their strength, should be thoroughly well trained physicians and surgeons. It is very desirable that they should have held a resident appointment at a general hospital, and have a good knowledge of practical surgery, gynaecology, tropical medicine, and the treatment of eye diseases. Useful information can be obtained from the secretaries of the various Missionary Societies, or from Thomas Cochrane, M.B., C.M., Honorary Secretary, British Advisory Board on Medical Missions, 1, Tudor Street, London, E.C.4.

## Dental Surgery.

UNTIL the passing of the Dentists Act, 1921, the profession of dentistry in this country was regulated by enactments very closely similar to those relating to the practice of medicine—that is to say, there was no direct prohibition of the act of practice; and the Dentists Act of 1878 gave the same degree of protection to legally qualified and registered dentists as was accorded to registered medical practitioners—namely, the reservation of the use of certain titles. This Act also provided (1) that no person should take or use the name or title of "dentist" (either alone or in combination with any other word or words) or of "dental practitioner," or any other name, title, or description expressed in words or by letters implying that he was specially qualified to practise dentistry, unless he was registered, under a penalty of £20; and (2) that an unregistered person could not recover any fee or charge in respect of any dental operation, attendance, or advice. But, in the case of the practice of medicine by unqualified and unregistered persons, certain deterrent factors came into play—such as the inability to give a death certificate—and these did not operate to the same extent in the case of dentistry; hence, unqualified practice was far more prevalent in dentistry than in medicine, and increased after a decision of the House of Lords placing a narrow interpretation upon the words "specially qualified to

practise dentistry," by defining the word "qualified" as not referring to competence but to the possession of a recognized diploma.

### THE DENTISTS ACT, 1921.

This unsatisfactory position has now been remedied by the passing into law of the Dentists Act, 1921; its provisions are based largely on the recommendations of a departmental committee appointed in 1917 by the Privy Council "to investigate the extent and gravity of the evils connected with the practice of dentistry and dental surgery by persons not qualified under the Dentists Act." Since November 30th, 1922, no person has been permitted by law to practise or hold himself out, whether directly or by implication, as practising or as being prepared to practise dentistry unless he is on the *Dentists Register* provided for by the Dentists Act, 1878. The practice of dentistry is defined as including "the performance of any such operation and the giving of any such treatment, advice, or attendance, as is usually performed or given by dentists," and the performing of any operation or the giving of any "treatment, advice, or attendance on or to any person as preparatory to or for the purpose of or in connexion with the fitting, insertion, or fixing of artificial teeth." The maximum penalty incurred by an unregistered dentist is £100 for each offence. There are, however, certain important exceptions to the requirement of registration. A registered medical practitioner may practise dentistry without being on the *Dentists Register*, and a registered pharmaceutical chemist or chemist and druggist may extract a tooth where the case is urgent and where no doctor or dentist is available, but the operation must be performed without any kind of anaesthetic; further, any person may carry out minor dental work in a public dental service under the personal supervision of a registered dentist provided it is in accordance with conditions approved by the Minister of Health after consultation with the Dental Board.

Certain persons other than those qualified by examination were entitled to be registered under the new Act. They had to be of good personal character and 23 years of age before July 28th, 1921 (the commencement of the Act), and to have been engaged for five of the seven years preceding that date as their principal means of livelihood in the practice of dentistry in the British Isles, or have been admitted to membership of the Incorporated Dental Society not less than one year before the commencement of the Act. The passing of "the prescribed examination in dentistry" within two years of the commencement of the Act is considered as equivalent to practising for five years, and a registered pharmaceutical chemist or a chemist and druggist who immediately before the commencement of the Act had a substantial practice as a dentist, including all dental operations, was treated as though he had practised for five years. A dental mechanic who for the five years had been carrying on his work as such and has secured the entry of his name on the list of candidates for examination can be registered provided within ten years of the commencement of the Act he passes the prescribed examination.

Dentistry may be carried on by a corporate body provided the majority of the directors and all the operating staff are registered dentists, and that no business other than dentistry or only some business ancillary to dentistry is carried on by the company. Companies carrying on the business of dentistry at the present time are permitted to continue to do so with certain restrictions, provided that the names of the directors have been entered in a list kept by the Registrar for that purpose. Every director or manager of a company convicted of an offence under the Act will be held to be guilty of the offence unless he proves that the offence was committed without his knowledge, and the court may, in addition to a fine, order that the name of any director convicted shall be removed from the list of directors aforesaid.

A subsequent Act passed in 1923 made provision for the registration of persons who were 21 in November, 1921, who had served during the late war in His Majesty's Forces, and were on that date engaged as their principal means of livelihood in the practice of dentistry in the British Isles. The Board, however, has no power now to consider any further applications under this Act.

### THE DENTAL BOARD.

The Dental Board of the United Kingdom was established for the purpose of administering the new Act. The first members of the Board, who held office for three years, were all appointed, but their term has now come to an end. The Board consists of: the chairman, appointed by the Privy Council; three members appointed by the General Medical Council, who must be members of the Branch Councils for England, Ireland, and Scotland respectively; three persons who are neither medical practitioners nor dentists, appointed to represent England, Scotland, and

Ireland; and six elected members, one of whom represents the qualified dentists in England and Wales, one those in Scotland, and one those in Northern Ireland, and two all the dentists registered under the Acts of 1921 and 1923.

On the establishment of the Dental Board in 1921 certain powers and duties of the General Medical Council were transferred to it, including the duty of erasing from the *Dentists Register* any entry which has been incorrectly or fraudulently made. An inquiry into the case of a person alleged to be liable to have his name erased from the *Register* is made by the Board, which reports its findings to the General Medical Council, the order directing the erasure being made, as at present, by the Council. A name erased from the *Register* can only be restored by the Council upon a report made by the Board. An appeal to the High Court may be made by any person aggrieved either by refusal of the Board to register his name or by the removal of his name from the *Register*. The administrative expenses of the Board are defrayed from the registration fees and annual retention fees, but any surplus may be allocated to purposes connected with dental education and research or to any public purpose connected with dentistry. The office of the Dental Board is at 44, Hallam Street, London, W.1.

The *Dentists Register* for 1926 contains the names of 14,199 persons, of whom less than a half are registered with qualifications, 8,095 names having been registered under the *Dentists Acts*, 1921 and 1923, and 6,194 with medical, surgical, or dental qualifications.

#### DENTAL EDUCATION AND EXAMINATION.

The preliminary examination in arts is the same for medical and dental students, and the early stages of their education embrace much the same subjects<sup>1</sup>; and, as the dental student is required to obtain a knowledge of the broad principles of medicine and surgery, it is necessary for him to pursue some portion of his studies at a medical school as well as at a special dental school, the latter not undertaking the teaching of these subjects. Registration as a dental student is not in all cases compulsory, though it is to be advised as convenient as affording proof of the commencement of professional education, and it is required by most of the licensing bodies, all of whom insist upon a curriculum covering four academic years.

Degrees in dentistry are granted by the Universities of Bristol, Durham, Leeds, Liverpool, Sheffield, Queen's University, Belfast, and the National University of Ireland, as will be found stated in the articles on these universities. Licences in dentistry entitling the holder to practise as a dental surgeon are granted by the following bodies: the General Medical Council, the Royal College of Surgeons in England, of Edinb., of Physicians and Surgeons of Glasgow.

Recognized dental schools are numerous. In London there are those connected with the Royal Dental Hospital, Leicester Square; the National Dental Hospital (now the University College Hospital Dental School), Great Portland Street; Guy's Hospital; King's College Hospital; and the London Hospital. In the provinces there are the Birmingham Dental Hospital; the Royal Infirmary and the General Hospital, Bristol; the Dental Hospital, and the Dental School, Liverpool; the Dental Hospital and School, Newcastle; the Dental Hospital, Sheffield. In Scotland there are the Dental Hospital, Dundee; the Incorporated Dental Hospital and School, Edinburgh; and the Incorporated Dental Hospital, Glasgow; and in Ireland, the Incorporated Dental Hospital of Ireland and the Royal College of Surgeons in Ireland.

There are considerable variations in the order in which the different licensing bodies require the various subjects of the curriculum to be taken up, and every prospective dental student should study, not only the regulations of the General Medical Council, but also those of the body whose licence he hopes to obtain. This is the more important as in the case of some licensing bodies changes in the curriculum have been made or are contemplated.

#### Recommendations of the General Medical Council.

The *Dentists Act* still leaves to the General Medical Council the duty of controlling the course of study and examinations required for dental qualifications.

The following recommendations as to the course of study and examinations to be required of candidates for degrees

or licences in dentistry or dental surgery were adopted by the Council on May 27th, 1922.

#### Preliminary Examination and Registration.

1. That every dental student shall, at the commencement of his studentship, be registered in the manner and under the conditions prescribed for medical students.

2. That before registration in the *Dental Students Register* every applicant shall be required to have passed, in addition to the examination in general education, which shall be the same as that required for medical students, an examination in *Elementary Physics* and *Elementary Chemistry*, conducted or recognized by one of the licensing bodies, which shall also be the same as that required for medical students.

3. That before registration as a dental student every applicant shall produce evidence that he has attained the age of 17 years.

#### Professional Study.

4. That every candidate for a degree or licence in dentistry or dental surgery shall be required before admission to the final or qualifying examination to produce certificates showing:

(i) That he is at least 21 years of age.

(ii) That he has been registered as a dental student.

(iii) That he has, subsequently to the date of registration as a dental student, been engaged in professional study for at least four years, of which three years at least shall be spent at a school or schools recognized for professional study by one of the licensing bodies.

(iv) That, subsequently to the date of registration as a dental student, he has attended at a recognized medical school courses of instruction, which shall be the same as those required for medical students, in the following subjects: (a) Chemistry, and (b) Physics, in their application to Medicine; (c) Elementary Biology. That he has attended at a recognized medical school courses of instruction in the following subjects: (d) Human Anatomy (with dissections and demonstrations) for three academic terms; (e) Physiology (with laboratory instruction, including Practical Histology) for two academic terms; (f) General Pathology (including Bacteriology) for two academic terms; (g) Medicine for two academic terms; (h) Surgery for two academic terms; (i) the practice of a recognized general hospital or hospitals of not less than eighty beds, with certified instruction in Clinical Medicine and Clinical Surgery, for four academic terms.

(v) That he has attended at a recognized dental school courses of instruction in the following special subjects: (a) Dental Anatomy and Physiology, human and comparative. The course should comprise a minimum of twenty meetings of the class. (b) Practical Dental Histology and Morbid Histology. The course should comprise a minimum of sixteen meetings of the class. (c) Dental Pathology and Surgery. The course should comprise a minimum of twenty meetings of the class. (d) Dental Materia Medica and Therapeutics. The course should comprise a minimum of sixteen meetings of the class. (e) Dental Metallurgy (with practical work and demonstrations). The course should comprise a minimum of twenty meetings of the class. (f) Dental Mechanics (with practical work and demonstrations). The course should comprise a minimum of twenty meetings and twenty demonstrations. (g) A course of instruction in the use of Anaesthetics, general and local, employed in dental practice. (h) A course of instruction in Radiology as applied to dentistry.

(vi) That he has for at least twenty-four calendar months attended, during the ordinary academic terms, the practice of a recognized dental hospital or of the recognized dental department of a general hospital.

(vii) That he has received for not less than twenty-four calendar months, or for 2,000 hours, practical instruction in dental mechanics.

#### Professional Examinations.

5. That the examination for a degree or licence in dentistry or dental surgery shall be partly written, partly oral, and partly practical, and shall include the following subjects: (a) Chemistry, Physics, and Biology, in their bearing on Medicine and Dentistry. (b) Human Anatomy and Physiology. (c) General Pathology, including Bacteriology. (d) Medicine and Surgery. (e) Dental Anatomy and Physiology, Dental Pathology, Dental Surgery (including Orthodontics), Dental Materia Medica and Therapeutics, and Dental Mechanics and Dental Metallurgy. (f) Practical Examination in Dental Surgery. (g) Practical Examination in Dental Mechanics and Metallurgy. (h) Anaesthetics, general and local, employed in dental practice.

6. That the prescribed subjects of examination may be combined or distributed at the discretion of the licensing bodies, and may be taken at two or more successive stages during the course of professional study: provided that no candidate shall be admitted to any final examination in dental surgery and dental mechanics until he shall have completed the required four years' course of study.

#### ACKNOWLEDGEMENT.

THE detailed information published in this Educational Number of the *BRITISH MEDICAL JOURNAL* for the benefit of intending students of medicine and newly qualified practitioners has been revised throughout with the co-operation of the deans and secretaries of the medical schools and kindred institutions and of officials in the several public services, to all of whom we wish to acknowledge our indebtedness.

<sup>1</sup> See the Registrar's Memorandum, printed in the article on the General Medical Council at page 418.

## Correspondence.

### MEDICAL ORTHODOXY.

SIR,—Mr. Hampson will, I am sure, not judge me wanting in appreciation of his wise counsels (*BRITISH MEDICAL JOURNAL*, August 21st, p. 329) when I find in his lecture a word that ought not, at least so it seems to me, to pass without open dissent. The word in question is "orthodoxy."

"Observance of the orthodox," he tells us, is of high importance in the medical profession; "unorthodox practices" are full of peril to the status and reputation of the practitioner; and wisdom should turn her eyes from beholding certain "illusive attractions" (some examples are quoted) "which are not to be regarded as orthodox."

The suggestion implied in these warnings plainly is that somewhere within the province of medicine there exists a recognized and authoritative standard of "orthodoxy"—that is, a body of doctrine and practice presented by authority and received and adopted as true and valid on the word of authority, with, as a corollary, and for the contumacious, the penalty of exclusion from the ranks and communion of the faithful. Possibly there are professions to which these propositions apply. But most certainly they do not apply to the profession of medicine.

On the contrary, while in medical life and thought there doubtless exist many opinions and practices more or less generally received and adopted, no one of these but is open to reasoned question and attack; and defence, if it is to be found, must be found in argument and demonstration and experiment, and not in official thunders or in the plea of convention or of constituted authority. Here, as elsewhere, the challenger of the opinion of a majority will need courage and perseverance, but if he is sincere and of good faith and can prove his case he will win through in the end. And even if he be left to plough a lonely furrow, neither anathema nor martyrdom awaits him.

It may be, as Mr. Hampson suggests, that certain "new cults" ought to be avoided. But if so, this is not because they teach "unorthodox" doctrine or practice, but because either they are obvious shams or frauds or the claims made on their behalf are not true or not proven.

Mr. Hampson, of course, speaks with great authority on the legal relations of medical practice, and here I am more than ready to go with him all the way. But when he urges a deferential submission to a medical "orthodoxy" that does not exist I am compelled, reluctantly but firmly, to call a halt.—I am, etc.,

London, W., Aug. 28th.

C. O. HAWTHORNE.

## Medical News.

THE membership of the British Medical Association now exceeds 32,000.

AFTERNOON lecture demonstrations on diseases of the eye begin on September 6th at the Central London Ophthalmic Hospital, and will continue for one month. On Tuesdays and Saturdays, at 11 a.m., from September 7th until October 2nd, the Bethlem Royal Hospital will hold a series of lecture demonstrations in psychological medicine. From September 13th to 25th the Infants Hospital will hold a special course in diseases of infants each afternoon; one visit will be made to the Thavies Inn Venereal Diseases Centre. Dr. Heald will give four demonstrations on treatment by electrotherapy on Wednesdays at the Royal Free Hospital, at 5.15 p.m., beginning on September 22nd. There will be a comprehensive whole-day course in orthopaedics at the Royal National Orthopaedic Hospital, from September 20th to October 2nd, and between the same dates the Westminster Hospital will hold an intensive all-day course in medicine, surgery, and the specialties. Early in October the National Hospital for Diseases of the Heart will give a fortnight's course; entries are limited to sixteen, so early application is advisable. Other courses starting the first week in October include a series of demonstrations on Tuesday and Thursday afternoons at the London School of Tropical Medicine, an all-day course at the Central London Throat, Nose, and Ear Hospital, and a practical operative

surgery class. Copies of all syllabuses, the general course programme, and the Fellowship Journal may be obtained from the Secretary of the Fellowship of Medicine, 1, Wimpole Street, W.1.

A PAMPHLET containing information about the post-graduate courses arranged by the Medical Faculty of the University of Vienna may be obtained free from the secretary of the Medical Lecture Courses, Schlösselgasse 32, Vienna VIII. Advice about lodgings is also given by the secretary.

THE annual dinner of past and present students of St. Mary's Hospital will take place at the Connaught Rooms on Monday, October 4th, at 7.30 p.m. Dr. G. W. H. French will be in the chair; the honorary secretary is Dr. A. Hope Gosse.

SIR FREDERICK WALKER MOTT, K.B.E., M.D., F.R.S., left estate of the gross value of £22,241 (net personally £16,862). After providing for certain legacies, including one of £50 to his assistant, Charles Geary, he left the residue upon trust for his wife for life, with remainder upon trust for his four daughters, with remainder to their respective issue, and failing these trusts, with remainder to the University of London for the endowment or partial endowment of a professorship of psychological medicine "at my Alma Mater," the Medical School of University College Hospital, stating that he did not wish the professorship to be founded until there should be sufficient accommodation for the study and treatment of early cases of mental disorder either by wards in University College Hospital or in an affiliated mental hospital.

Dr. Montague H. Way and Dr. A. Bosworth Wright have been added to the Commission of the Peace for the city of Portsmouth by the Lord Chancellor. Dr. Way, who was born at Portsmouth, was educated at Guy's Hospital, and obtained the diplomas of M.R.C.S. and L.R.C.P. in 1897. He has been in practice at Southsea for twenty-six years. He was chairman of the Portsmouth Division of the British Medical Association in 1924, and is a member of the Portsmouth Insurance Committee and chairman of the Panel Committee. In 1921 he was elected a member of the Portsmouth Town Council. Dr. A. Bosworth Wright was a student at the London Hospital, and obtained the diplomas of M.R.C.S., L.R.C.P. in 1896. He is surgeon to the Royal Portsmouth Hospital.

SIR JOHN WILLIAMS, Bt., formerly obstetric physician to University College Hospital, London, who died on May 24th last, aged 85, left estate of the gross value of £123,742, with net personally £121,012. He bequeathed £2,000 to University College Hospital and £1,550, together with any of his books, pictures, manuscripts, etc., his executors may select, to the National Library of Wales. The residue of his property, which it is believed will amount to nearly £100,000, will be divided between the National Library of Wales and the University College of Wales, both at Aberystwyth.

THE seventh Italian Congress of Industrial Medicine, which was to have been held at Genoa from October 11th to 12th, has been postponed until next year.

A POST-GRADUATE course on the diagnosis and treatment of cancer will be held at Strasbourg from October 18th to November 6th. The fee for the course will be 250 francs, and applications should be addressed to Dr. Gunsett, Cancer Department, Civil Hospital, Strasbourg.

FOR the convenience of medical men desiring information concerning the spas of France arrangements have been made for an office to be opened adjacent to the British Medical Association House. Mme Juppé-Blaise, who has had charge of this department in the Office Français du Tourisme, will give personal attention to all inquiries, will forward detailed information, and will arrange travelling, hotel, or other accommodation. For the present inquiries should be addressed to Mme Juppé-Blaise, c/o the Financial Secretary, B.M.A. House, Tavistock Square, W.C.1.

PARLIAMENT reassembled on August 30th and approved the continuance of the emergency regulations during the month of September. The House of Lords adjourned at once, but the House of Commons on the following day had a discussion on the stoppage in the coal-fields and then adjourned to November 9th. It may, however, be recalled at the end of September if the coal dispute is not settled. No allegation was made that there was any abnormal sickness in the coal-fields. The Government intends to take up the Births and Deaths Registration Bill during the autumn session, and it is expected that the measure will become law. In reply to a question the Minister of Health gave the information with regard to the treatment of persons suffering from the after-effects of lethargic encephalitis which was published last week (p. 398) in the notice of the Report of the Metropolitan Asylums Board, and recalled that a bill had been introduced to amend the Mental Deficiency Act so as to facilitate the admission into mental deficiency institutions of cases suitable for treatment therein.

SEPT. 4, 1926]

# The British Medical Association: ITS AIMS, WORK, AND CONSTITUTION.

THE British Medical Association, as stated in our introductory article on the Profession of Medicine, was founded in 1832 to promote the medical and allied sciences, to maintain the honour and interests of the profession, and to foster a feeling of friendship among its members. To attain these objects it holds periodical meetings for the discussion both of medical and scientific subjects and of professional affairs; it publishes the *BRITISH MEDICAL JOURNAL*; it maintains a reference and lending library; it has instituted lectures, and scholarships and grants for research. It thus concerns itself with every side of medical work—science, clinical medicine, public health, and the material interests of professional life. The British Medical Association, with a membership now of more than 32,000, is the oldest, largest, and most powerful British organization devoted to the welfare of the medical profession. It has recently acquired a fine building in Tavistock Square, London, for its headquarters, providing ample accommodation for immediate needs and space for future developments. These new premises, designed by Sir Edwin Lutyens, R.A., by His Majesty the King, accompanied by the Queen; and the beautiful wrought-iron gates erected as a memorial to the 574 members who fell in the war, by which the quadrangle is completed, were dedicated on that occasion by the Archbishop of Canterbury. The need for larger accommodation had become insistent owing to the remarkable growth in the central work of the Association during recent years, which had far outstripped the capacity of the premises at 429, Strand, which have now been acquired by the Government of New Zealand for its London offices.

## Constitution and Administration.

The Association has Branches and Divisions throughout Great Britain and Ireland, and also in the Dominions, Colonies, and Dependencies. The Divisions are arranged territorially, and number, in all, 280. For certain purposes of administration or of scientific and clinical work, the Divisions are combined into 93 Branches. Members of Divisions elect representatives on the Branch Councils and also a member or members of the Representative Body, which is the governing body of the Association and determines its policy.

The Council is the executive of the Association. It is elected partly by the Divisions and Branches and partly by the Representative Body, and includes representatives of the Navy, Air Force, Army, and Indian Medical Services elected by the Representative Body. The Representative Body and Council elect standing committees to take charge of different subjects. Among these may be mentioned the Science, Medico-Political, Ethical, Hospitals, Public Health, and Naval and Military Committees. There are Committees also for the Dominions, Scotland, Ireland, and Wales; and for the working machinery of the Association, such as the Organization, Finance, and Journal Committees. The Insurance Acts Committee, elected partly by the Association and partly by insurance medical practitioners, is financed by the Association; it is the recognized executive and mouthpiece of the insurance practitioners of Great Britain.

## Privileges of Members.

- A member of the Association has the right—
1. To attend the annual and other general meetings of the Association and the meetings of the Division and Branch to which he or she belongs.
  2. To take part by personal vote (or in some Divisions by voting paper) in the election of the representative of his or her Division in the Representative Body, and also in the election of members of the Council.
  3. To receive by post the *BRITISH MEDICAL JOURNAL*, published weekly, which gives a full record, with commentary, of progress in clinical and scientific medicine and of medico-political affairs throughout the British Empire.
  4. To receive the help and advice of the central office in any professional difficulty.
  5. To use the Library as a reading room, and to borrow current medical or scientific books on payment of postage. Besides modern works and periodical medical literature—foreign as well as English—the library contains many books of historic interest.

The full benefits of the Association can only be secured by the co-operation of large numbers of the medical profession, for the greater the membership and the funds the more efficient the organization.

The Association during the past ninety-four years has been the direct means of benefiting every class of medical men and medical women. In asking for new members it looks not only to the older practitioners but also and especially to those recently qualified. To these a generous concession is made as regards subscription, and there is a special claim to their recognition of the work of the Association in improving the conditions under which they may hold appointments in the public services or in civil life. The Association's work for

COURT OF HONOUR, FROM SOUTH-WEST ANGLE.

the Services is well known. It feels a special responsibility towards those members of the profession who by reason of their position are precluded from taking common action, and the events of this year have proved again its capacity to further their interests.

## Subscriptions and Applications for Membership.

The ordinary subscription to the British Medical Association is 3 guineas a year for members resident in the British Isles, but this is subject to various exceptions. Thus, newly qualified practitioners elected within two years of registration pay half this sum up to the end of the fourth year after registration; medical officers on the active list of the R.N., R.A.F., R.A.M.C. (Regular), and I.M.S. pay 2 guineas; concessions are made also to members (in the British Isles) of forty years' standing, to members of ten years' standing who have retired from practice, to medical married couples residing together, and to whole-time teachers and research workers. The ordinary subscription for members living abroad is 1½ guineas, but some Branches have special local subscriptions. A member elected after June 30th pays half the subscription for that year.

All duly qualified British medical practitioners are eligible for election. Full particulars can be obtained from the Medical Secretary, British Medical Association House, Tavistock Square, London, W.C.1; the Scottish Medical Secretary, 6, Drumshugh Gardens, Edinburgh; or the Irish Medical Secretary, 16, South Frederick Street, Dublin.

## ASSOCIATION NOTICES.

## Association Notices.

## BRANCH AND DIVISION MEETINGS TO BE HELD.

CAPE OF GOOD HOPE (WESTERN) BRANCH.—A case night arranged by Mr. T. Lindsay Sandes and Dr. G. B. Wilkinson will be held at 35, Wale Street, Capetown, on Friday, September 24th, at 8 p.m.

SURREY BRANCH: REIGATE DIVISION.—The following programme has been arranged for the session 1926-27: Wednesday, October 6th, 1926, at 7 p.m., Annual Dinner, White Hart Hotel, Reigate, followed by Mr. Percy Sargent, C.B., on The management of patients with brain tumours. Wednesday, November 10th, at 4.30 p.m., Meeting at the East Surrey Hospital, Reigate, followed by Dr. H. W. Barber: The treatment of some common diseases of the skin. Tuesday, December 14th, at 8.45 p.m., Dr. Stoddart: The certification of mental patients. Tuesday, February 8th, at 8.45 p.m., Sir William Wilcocks, C.B., C.M.G.: The etiology and treatment of fibrositis (chronic rheumatism). Tuesday, March 8th, at 8.45 p.m., Dr. Stanley Dodd: Gynaecology. Wednesday, April 13th, at 4 p.m., Clinical Meeting at Caterham Cottage Hospital. May 11th, at 4 p.m., Annual Meeting. All meetings will be held at the East Surrey Hospital unless otherwise stated.

## VACANCIES.

BIRMINGHAM MATERNITY HOSPITAL.—(1) Honorary Assistant Physician, and (2) Honorary Anaesthetist.  
BOOLE BOROUGH HOSPITAL.—(1) Senior Medical Officer. Salary for (1) £150, and for (2) £125 per annum each.  
BRIGHTON: ROYAL SUSSEX COUNTY HOSPITAL.—House-Surgeon (male). Salary £150 per annum.  
BURMA RAILWAYS CO., LTD.—District Medical Officer. Salary Rs.1,200 per mensem, rising to Rs.1,600.  
CARDIFF: PRINCE OF WALES'S HOSPITAL.—House-Surgeon for Cripples' Officer. Salary £100 per annum.  
CHESTERFIELD AND NORTH DERBYSHIRE ROYAL HOSPITAL.—Resident Surgical Officer. Salary £300 per annum.  
DEVONPORT: ROYAL ALBERT HOSPITAL.—House-Surgeon. Salary £150 per annum.  
DOVER: ROYAL VICTORIA HOSPITAL.—House-Surgeon. Salary £180 a year.  
EVERT: ROYAL DEVON AND EXETER HOSPITAL.—(1) House-Physician, and for (3) £100.  
HAMPSHIRE: PARISH OF ST. JOHN.—Junior Resident Assistant Medical Officer at the New End Hospital. Salary £150 per annum.  
LEICESTER ISOLATION HOSPITAL AND SINTORIUM.—Resident Medical Officer. Salary £350 per annum.  
LEICESTER ROYAL INFIRMARY.—House-Surgeon. Salary at the rate of £125 per annum.  
MANCHESTER BABIES HOSPITAL, Burnage Lane, Levenshulme.—(1) Resident Medical Officer. (2) Resident Clinical Assistant. Salaries at the rate of £125 and £50 per annum respectively.  
NEWCASTLE-ON-TYNE: HOSPITAL FOR SICK CHILDREN.—Honorary Assistant Surgeon.  
O-WESTRY: SHROPSHIRE ORTHOPEDIC HOSPITAL.—Two House-Surgeons. Salary £150 per annum.  
OXFORD: RUDCLIFFE INFIRMARY AND COUNTY HOSPITAL.—Resident Medical Officer to the Osler Pavilion for the Treatment of Tuberculosis. Salary at the rate of £120 per annum.  
ROCHDALE INFIRMARY AND DISPENSARY.—Junior House-Surgeon (male). Salary £200 per annum.  
ROCHESTER: ST. BARTHOLOMEW'S HOSPITAL.—Honorary Pathologist. Honorarium £150 per annum.  
ROYAL MANCHESTER CHILDREN'S HOSPITAL, Pendlebury.—(1) Resident Medical Officer. (2) Resident Surgical Officer. (3) Assistant Medical Officer for Out-patient Department. Salary at the rate of £120, £80, and £150 per annum respectively.  
ROYAL NATIONAL ORTHOPEDIC HOSPITAL, Great Portland Street, W.1.—House-Surgeon (male). Salary £150 per annum.  
ST. HELEN'S COUNTY BOROUGH.—Assistant Medical Officer of Health (male). Salary at the rate of £650 per annum, rising to £750.  
ST. HELEN'S HOSPITAL.—Resident Medical Officer. Salary £250 per annum.  
ST. JOHN'S HOSPITAL, Lewisham, S.E.13.—Casualty Officer. Salary £100 per annum.  
ST. MARY'S HOSPITAL, W.2.—Assistant Medical Officer in Charge of X-Ray Department.  
ST. PETER'S HOSPITAL FOR STONE, ETC., Henrietta Street, W.C.2.—House-Surgeon. Salary at the rate of £75 per annum.  
SUMMITT FREE HOSPITAL FOR WOMEN, Marylebone Road, N.W.1.—House-Surgeon. Salary at the rate of £100 per annum.  
SURREY'S HOSPITAL SOCIETY, Greenwich.—House-Physician and House-Surgeon at Dreadnought Hospital. Salary £110 per annum with proportion of fees.  
SURREYFIELD ROYAL INFIRMARY.—Assistant Casualty Officer. Salary at the rate of £80 per annum.  
SUSSEX MATERNITY AND WOMEN'S HOSPITAL, Brighton.—House-Surgeon. Salary £125 per annum.  
SURREY UNIVERSITY, New South Wales.—Professorship of Psychiatry. Salary £1,100 per annum.  
WARRINGTON INFIRMARY AND DISPENSARY.—Senior House-Surgeon (male). Salary £150 per annum.  
WEST END HOSPITAL FOR NERVOUS DISEASES, Gloucester Gate, Regent's Park, N.W.1.—Junior House-Physician (male). Salary £100 per annum.  
WEST LONDON HOSPITAL, Hamamsmith Road, W.6.—(1) House-Physician. (2) Two House-Surgeons (males). Salary at the rate of £100 per annum each.  
WEST NORFOLK AND KING'S LYNN HOSPITAL.—Resident Surgical Officer. Salary £200 per annum.

WESTERN OPHTHALMIC HOSPITAL, Marylebone Road, N.W.1.—(1) Senior and (2) Junior non-resident House-Surgeons. Salaries at the rate of £150 and £100 per annum respectively. (3) Honorary Assistant Surgeon. Honorarium 100 guineas per annum.

CERTIFYING FACTORY SURGEONS.—The following appointments are vacant: Measham (Leicestershire), Thame (Oxfordshire), Newhaven (Sussex). Applications to the Chief Inspector of Factories, Home Office, Whitehall, S.W.1.

This list of vacancies is compiled from our advertisement columns, where full particulars will be found. To ensure notice in this column advertisements must be received not later than the first post on Tuesday morning.

## POST-GRADUATE COURSES AND LECTURES.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—Central London Ophthalmic Hospital, Judd Street, W.C.1: Series of lecture demonstrations every afternoon for one month on all branches of ophthalmology. Bethlem Royal Hospital, St. George's Fields, S.E.1: Course in psychological medicine, beginning September 7th, every Tuesday and Saturday at 11 a.m. Copies of syllabuses of above courses and information on post-graduate work generally is obtainable from the Secretary of the Fellowship of Medicine, 1, Wimpole Street, W.1. Post-Graduate Hostel, Imperial Hotel, Russell Square, W.C.1.—Wed. 9 p.m., Manipulative Surgery and the Bone-setter. Thurs. 9 p.m., The General Practitioner and the Medical Officer of Health. GLASGOW POST-GRADUATE MEDICAL ASSOCIATION.—At Western Infirmary: Daily, 9.30 a.m., Clinical Medicine; 10.45 a.m., Clinical Surgery. Tues. and Thurs. 4 p.m., Radiology; 5.30 p.m., Venereal Diseases. At Royal Fever Hospital: Mon., Wed., and Fri., 9.15 a.m., Infectious Fevers. At Royal Hospital for Sick Children: Mon., Wed., and Fri., 3.30 p.m., Surgical Diseases of Children. At Eye Infirmary: Mon., Wed., and Fri., 2 p.m., Diseases of the Eye.

## BIRTHS, MARRIAGES, AND DEATHS.

The charge for inserting announcement of Births, Marriages, and Deaths is 9s., which sum should be forwarded with the notice not later than the first post on Tuesday morning, in order to ensure insertion in the current issue.

## MARRIAGES.

DAVIDSON.—BRUSH.—At Maxwelltown U.F. Church, Dumfries, on August 24th, 1925, John Polson Davidson, M.C., M.B., Ch.B., to Jessie Ronald Brash, M.B., Ch.B. At Home, Deveron House, Clayton-le-Moors, October 29th and 30th, 1925.  
GUTHRIE.—HICKSON.—On August 28th, at St. Mary Abbott's, Kensington, Gerrans Leftwich Guthrie, son of the late Hugh Guthrie, Esq., and of Mrs. Phillips, to Sylvia Kema Hickson, M.D., M.R.C.P., daughter of Professor and Mrs. Hickson of 26, Barton Road, Cambridge.  
WILSON.—JOHNSON.—On August 26th, at the Parish Church, Aine, Yorks, Charles Haddon Wilson, M.B., Ch.B., son of Mr. and Mrs. G. C. Wilson, "The Hollies," Normanton, to Hope Evelyn Johnson, B.A. Cantab., niece of Dr. and Mrs. L. A. Johnson, "The Meads," Tollereton.

## DEATHS.

ARMSTRONG.—On August 21st, 1926, at "The Moat," Yoxall, Burton-on-Trent, Frank Greasley Armstrong, M.R.C.S., L.S.A., aged 63 years.  
FRASER.—At Raipur, India, on August 19th, of cholera, Lieut.-Colonel W. J. Fraser, F.R.C.S.E., I.M.S., third son of the late John Fraser, Abbotford, Ceylon, and Wolf Crag, Bridge of Allan, aged 45.  
REID.—On August 21st, 1926, Dr. James Reid, late of Banbury, closest son of A. P. Reid, Belfast, Ireland, aged 43.

[The present issue being the Annual Educational Number, much current material is held over, and neither the "Supplement" nor the "Epitome of Current Medical Literature" is published this week.]

COINCIDENT DUODENAL AND GASTRIC  
ULCER.

(With Special Plate.)

BY

D. P. D. WILKIE, M.Ch., F.R.C.S.,

PROFESSOR OF SURGERY, EDINBURGH UNIVERSITY.

The surgical treatment of duodenal and gastric ulcer is still the subject of controversy, and opinion is sharply divided as to the exact place which surgery should hold, and will ultimately maintain, in the treatment of this disorder. There is, however, an imposing accumulation of evidence of the curative action of a gastro-enterostomy in cases of duodenal ulcer. Collective statistics show that complete relief from symptoms follows in 85 per cent. of cases of duodenal ulcer following gastro-enterostomy. For gastric ulcer, on the other hand, this operation is much less successful, and most surgeons are agreed that when the ulcer is situated on the lesser curvature of the stomach a direct attack on it of one kind or another is essential for a lasting cure.

The object of this paper is not to analyse the causes of non-success following gastro-enterostomy for duodenal ulcer further than to point out the frequency with which a coincident ulcer is present in the stomach, an ulcer which is liable to escape observation unless a systematic search is made for it. During the three years prior to the war I examined in the *post-mortem* room 490 bodies for duodenal ulcer. In 41 bodies one or more duodenal ulcers were found—that is, in 8 per cent. In 5 cases one or more gastric ulcers were present along with the duodenal ulcers—that is, in 12 per cent. of cases of duodenal ulcer a coincident gastric ulcer was found (Fig. 1). Whilst, therefore, fully aware of the frequent association of ulcer in both stomach and duodenum, I confess to have omitted to make a systematic examination for multiple ulcers in all upper abdominal operations until five years ago, when the following case brought home to me the importance of a complete assessment of pathology at operation.

## CASE.

A man, aged 28, had been operated on two years previously for a perforated duodenal ulcer. The perforation had been closed and the pelvis drained. For two months after the operation he had been free from symptoms, and then the typical periodic attacks of indigestion had returned.

At the second operation, performed in July, 1920, a chronic duodenal ulcer on the anterior wall of the duodenum, with considerable stenosis, was found. Posterior gastro-enterostomy was performed, and two months later the patient expressed himself as being relieved but not cured of his dyspeptic symptoms. In 1921 he returned still complaining of intermittent dyspepsia. A jejunal ulcer was suspected, and a third operation was carried out just one year after the second. No jejunal ulcer was found, the duodenal ulcer had healed, but high up on the lesser curvature of the stomach there was a large, chronic, indurated, penetrating ulcer, obviously of long standing. The base of the ulcer was burnt out with the cautery and the edge sutured and invaginated. For the five years since this operation the patient has been free of all symptoms.

It appeared to me to be quite clear that this patient had had all along coincident gastric and duodenal ulcers, and that until the last (third) operation treatment had been directed only to the latter. A direct attack on the gastric ulcer was followed by a symptomatic cure. Since this lesson I have made a systematic examination for gastric ulcer at all operations for duodenal ulceration. During this period I have operated on 300 cases of ulcer, and the results of the five years' experience are as follows:

|                                       | Male. | Female. | Total. |
|---------------------------------------|-------|---------|--------|
| Duodenal ulcer alone ...              | 167   | 51      | 221    |
| Gastric ulcer alone ...               | 17    | 20      | 37     |
| Coincident duodenal and gastric ulcer | 27    | 15      | 42     |
| Totals... ..                          | 211   | 83      | 300    |

Some interesting points emerge in regard to the sex and age incidence of ulcer from this series of 300 cases.

The common occurrence of coincident gastric and duodenal ulcer is clear—namely, that in 16 per cent. of duodenal ulcer cases there was present a gastric ulcer as well; and in 53 per cent. of cases with gastric ulcer one or more duodenal ulcers were found. If the cases of coincident gastric and duodenal ulcer be excluded, we find that duodenal ulcer was exactly six times as frequent as gastric. In the male subject the proportion of duodenal to gastric ulcer was 9 to 1, in the female 2.7 to 1. If all ulcer cases be included, the proportion of duodenal to gastric ulcer is 3.3 to 1. In the male sex it is 4.4 to 1, in the female sex 2 to 1. We may fairly deduce from these figures that, given the factors predisposing to ulceration, the probable site of ulcer will be the first part of the duodenum and after this the lesser curvature of the stomach.

## DIAGNOSIS.

It is often very difficult from the patient's history and ordinary clinical examination to be sure whether he is suffering from a gastric or a duodenal ulcer, or both. When, however, the pain comes on at varying intervals after food, whilst still displaying the periodicity so constantly found with ulcer, one has some grounds for suspecting that ulcers may be present in both stomach and duodenum. The x-ray picture after a barium meal is the real aid to accurate diagnosis. In the early cases the x-ray evidence of the gastric ulcer may be a little uncertain, and be confined to a slight irregularity of outline of the lesser curvature with some degree of spasmodic hour-glass contraction. In the later cases, where stenosis has occurred, the very typical picture of hour-glass stomach and duodenum leaves no doubt as to the diagnosis (Fig. 2).

## TREATMENT.

There can be little doubt that under prolonged and efficient medical treatment many early cases of gastric and duodenal ulcer can be completely cured. More often than not, however, the patient either does not seek, does not get, or will not submit to the prolonged rest and strict dietary until he has had numerous attacks, which have led to definite organic changes in the gastric or duodenal wall. When such changes have occurred the hope of a lasting cure by medical measures alone is distinctly less, and if one course of medical treatment is followed by relapse operative measures should be considered. We are concerned here merely with the surgical treatment of coincident ulcers in the stomach and duodenum. From the experience of the 42 cases dealt with in this paper, in the treatment of which a considerable variety of surgical measures have been employed, I should, in the first place, divide the cases roughly into two classes:

1. Comparatively early cases with active ulceration but little or no stenosis.
2. Old-standing cases with marked stenosis, often in elderly people.

In Class 1 the operation must include the extirpation of the gastric ulcer, either by partial gastrectomy, excision, or cautery, together with some form of gastro-enterostomy. In Class 2 the clinical and the pathological picture are both dominated by the stenoses and their results, and anastomotic operations, without any direct attack on the ulcers, are followed by the most gratifying and lasting success. This latter fact is of importance, as in many cases the patients are old, thin, and feeble, and not well suited for drastic surgical procedures. In 18 of the 42 cases in this series the patients were over 50 years of age, in 3 cases the patients were over 70 years of age, yet all made excellent recoveries after multiple anastomotic operations.

It may be asked what safeguard we have against the malignant degeneration of the ulcer if such conservative measures are adopted. My experience has been that, whilst malignant disease may arise in a gastric ulcer (in one case of this series it was found and proved fatal), it does not arise in the cicatrizing type which leads to hour-glass contraction, and the risk of it may be regarded as a negligible factor in determining the operative procedure in these old-standing stenosing cases.

The correct method of dealing with cases in the first group, where active ulcers are present in both stomach

and duodenum, is not an easy matter to decide. A resection of the whole ulcer-bearing area, whilst a logical procedure, is rendered difficult in many cases by the fixity of the duodenum. It was only carried out in two cases

TABLE I.—Operative Treatment in 42 Cases of Coincident Gastric and Duodenal Ulcer.

| Operation.   | No. of Cases. | Result. | Present State.  |
|--|---------------|---------|---|
| Posterior gastro-enterostomy ...                                   | 7             | 7 R.    | 3 perfectly well; 4 still complain of gastric symptoms. |
| Anterior gastro-enterostomy and lateral anastomosis                | 3             | 3 R.    | 2 very well; 1 still complaining.                       |
| Gastro-duodenostomy ...  | 1             | 1 D.    | Death from pulmonary embolism on tenth day.             |
| Excision of ulcer and posterior gastro-enterostomy                 | 2             | 2 R.    | 1 very well; 1 late recurrence of symptoms.             |
| Excision and anterior gastro-enterostomy                           | 1*            | 1 D.    | Death few hours after operation.                        |
| Excision and gastro-duodenostomy                                   | 1             | 1 R.    | Patient very well.                                      |
| Cautery and posterior gastro-enterostomy                           | 15            | 15 R.   | All very well.  |
| Cautery and gastro-duodenostomy                                    | 1             | 1 R.    | Very well.  |
| Pyloroplasty ...   | 1             | 1 R.    | Very well.  |
| Double gastro-enterostomy and lateral anastomosis                  | 1             | 1 R.    | Very well.  |
| Gastro-gastrostomy and posterior gastro-enterostomy                | 2             | 2 R.    | Both very well.   |
| Gastro-gastrostomy and gastro-duodenostomy                         | 1             | 1 R.    | Very well.  |
| Gastro-gastrostomy and gastro-duodenostomy and duodeno-jejuno-tomy | 1             | 1 R.    | Very well.  |
| Pyloric exclusion and gastro-enterostomy                           | 1             | 1 R.    | Very well.  |
| Posterior gastro-enterostomy and duodeno-jejuno-tomy               | 1             | 1 R.    | Very well.  |
| Partial gastrectomy ...  | 2             | 2 R.    | Both very well.   |
| Exploratory operation ...  | 1†            | 1 R.    | Death some months later.                                |

\* Perforated.

† Malignant.

patients in this group of their freedom from all subsequent digestive trouble. So favourable were the reports in this group that I now regard the Balfour operation as that of choice for the early, active cases of coincident gastric and duodenal ulcer.

There were two deaths in this group of 42 cases. In one case death occurred suddenly on the tenth day, from pulmonary embolism. In the second case, that of an elderly lady, the gastric ulcer had perforated eight hours before operation, and death resulted from general peritonitis. A death rate of 4.8 per cent. cannot be regarded as high when it is considered that in many of these cases one is dealing with old and emaciated subjects.

The great variety of operations which were carried out in this series of cases is illustrated in Table I and Fig. 3.

#### CONCLUSIONS.

1. Coincident ulceration in stomach and duodenum is relatively common.

2. In this series it occurred in 16 per cent. of all duodenal ulcers and in 53 per cent. of all gastric ulcers.

3. Two groups of cases are to be distinguished when considering operative measures: (a) active ulcers without stenosis in relatively young people (below 50); (b) unhealed but cicatrized ulcers with stenosis in elderly subjects.

4. The Balfour operation is recommended for Class (a). Purely anastomotic operations give a lasting symptomatic cure in Class (b).

## MAN AS THE INTERMEDIATE HOST OF THE TAENIA SOLIUM.

(With Special Plate.)

BY

E. J. H. ROTH, M.R.C.S. ENG., L.R.C.P. LOND.,  
D.M.R.E. CAMB.,

CHIEF ASSISTANT IN THE X-RAY DEPARTMENT, ST. BARTHOLOMEW'S  
HOSPITAL, LONDON; RADIOLOGIST TO THE ESSEX COUNTY  
HOSPITAL, COLCHESTER.

INFECTION by the *Taenia solium* has become extremely rare in this country, and the recognition of the aberrant *Cysticercus cellulosae* stage of this intestinal parasite in man by radiological means is of interest.

The *Taenia solium* used to be commoner, and was described at a period when x radiations were not being employed in medicine, and it has not been found possible to discover a record of appearances which may be seen in radiograms when man becomes the intermediate host. The condition is well recognized, and not of rare occurrence at the present day in many parts of the world, notably in Germany, in some parts of America, and in India, and I hope that the publication of this case will give me access to additional information upon this interesting subject, and that I may receive references to cases which have been seen.

The tapeworm known as the *Taenia solium* is characterized by a scolex bearing four somewhat prominent suckers and hooklets, varying in number from twenty-six to twenty-eight. It is an extremely long parasite, and lies in the intestinal tract of man, who is the host, the intermediate host being the pig. The proglottides contain the ova, and as they ripen are discharged in the faeces, the ova retaining a certain motility, and are swallowed by the pig. The gastric juices of the intermediate host act upon the shell of the ovum and dissolve it, and the oncosphere, which is set free in the stomach, passes into the blood stream, whence it is carried all over the body. It may settle in the brain, either in its substance or in the meninges, in the lungs, in the heart, in the eye, but most commonly in the skeletal muscles. It rarely lodges in the substance of the liver. It soon becomes transformed into a clear elliptical cyst, measuring about a centimetre by half a centimetre, and if lying in muscle substance takes up a position with its long axis parallel to the fibres of the muscle, which it separates. It slowly degenerates and becomes calcified, and may become apparent and give rise to symptoms and signs. Osler reports a case in which hundreds of subcutaneous nodules proved to be calcifications of the *Cysticercus cellulosae*, and many cases in which these bodies

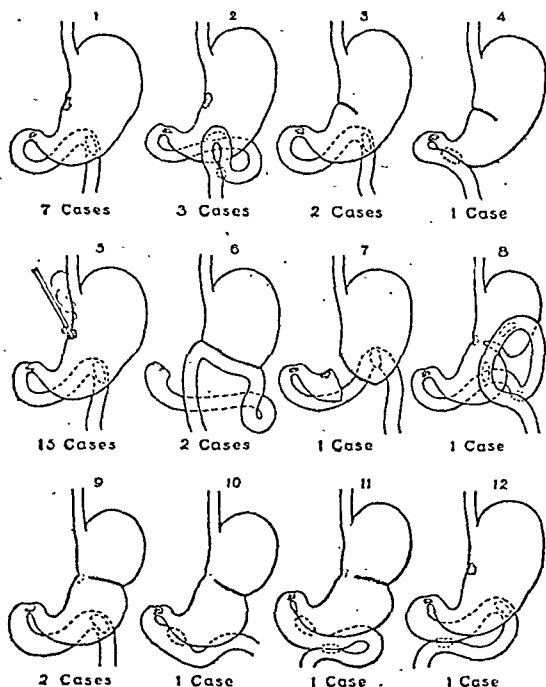

FIG. 3.—Diagrammatic drawings of operations carried out in the 42 cases dealt with. Below each diagram the number of cases so dealt with is stated.

in this series. Simple gastro-enterostomy alone is insufficient, and will be followed by persistent symptoms in 50 per cent. of cases. Burning out the ulcer with the thermo-cautery, followed by invagination and a gastro-enterostomy, was carried out in 15 cases, and with uniform success. I confess to a pleasant surprise on hearing from the

have been seen in the retina have been reported from the German clinics.

It happens, then, that man may become the intermediate host, and because of the consequences the condition is a serious one. There are various theories as to how this may occur. The usual reasoning is that man may eat some vegetables or drink water contaminated with the segments or ova and thus become the intermediate host (or pig), with the same cycle of development of the parasite. It can occur, however, that man is both the host and intermediate at the same period; that is to say, that a man infected with the *Taenia solium* may also be infected with the *Cysticercus cellulosae*. It is thought that this accident may be caused through the regurgitation of the ripe proglottides into the stomach in an act of vomiting, but it is more likely that the irritation of the proglottides passing from the anus, which they may do spontaneously and under their own motility, leads to the soiling of man's fingers and the transference of the ova to the mouth.

A man, aged 44 years, a hairdresser, was sent to me for consultation by his doctor in April, 1925. He complained of pains in the left knee joint of some five years' duration which he described as "rheumatic." A sinus had developed upon the medial surface of the knee some two months before I saw him; it was about a centimetre in diameter and of about the same depth, and there was a purulent discharge from it. For the last ten years the patient had suffered from "fits" of epileptiform type at approximately monthly intervals. He would lose consciousness and fall down in the street. He did not recollect having bitten his tongue during one of the seizures. It was on account of these fits that he was discharged from the army, the condition being thought to be due to neurasthenia following shell-shock. He was in India from 1903 until 1911 in the army, from which he was discharged in 1916 after active service in France. There was no history of infection by intestinal parasites.

The man appeared to be healthy. There was a discharging sinus upon the medial aspect of the left knee. The chest appeared to be normal; special attention was paid to the rhythm of the heart as cases have been reported where it was irregular when the heart muscle contained the *Cysticercus cellulosae*. No abnormality was found in the eyes, and no subcutaneous nodules could be felt.

Radiograms were taken of the left knee-joint and the condition shown in Fig. 1 was discovered. Scattered throughout the muscles around the knee-joint were some eighty opaque, ovoid, disc-like bodies, which were doubtlessly in the nature of calcifications. They measured about 1 cm. by 5 cm., with regular edges. The centre of each mass was less dense than the peripheral margins, where the shading was "ringed" and concentric.

It was decided to examine every other part of the body, and this was done. Radiograms selected from this examination are reproduced in Figs. 2 to 4; some of the others yielded negative results. It will be seen that a similar condition to the one found in the knee exists in nearly every part, but with the main grouping of the calcifications in the extremities, as far down as the ankles and the wrists. The pectoral group of muscles upon each side contained a large number, and they were also found in the muscles of the neck and in the deep muscles around the vertebral column. The lungs were apparently unaffected and no abnormality could be detected in the heart shadow. None was located in the liver substance. Three, at least, of the bodies were seen to be lying in the pia mater of the brain, one of which was localized in the middle of the motor area upon the left side. These cerebral calcifications were similar to those seen in the other parts, and were not irregular, branched, or of undue size, as they have been described as seen in some autopsies. A calcification was localized as lying at the bottom of the sinus in the left knee-joint, which was thus explained.

It was determined to remove one of the bodies for pathological investigation, and a superficial one in the right forearm was localized and taken out under a local anaesthetic. It was creamy white, uniformly regular in consistency, and of stony hardness. Sections were prepared after decalcification, and the photomicrographs which were taken of them are reproduced in Figs. 5 and 6.

Under a low objective the majority of the section was seen to consist of degenerated keratinous material, surrounded by a fibrous capsule in intimate association with the muscle substance in which it was embedded. In the portion of the section which is reproduced an area of specialized tissue was seen, which, under a higher power of magnification, was found to consist of what is doubtlessly a cestode head with its four suckers and its hooklets, representing in every respect the degenerated scolex of the *Taenia solium*. This is well shown in Fig. 6.

It was thus established that the sinus formation in the left knee-joint and the "fits" from which the patient had suffered for so many years were caused by infection by the *Cysticercus cellulosae* stage of the *Taenia solium*, of which he was the intermediate host. It is to be supposed that he became infected whilst in India, and that as the calcification process was completed in the embryonic deposits the manifestations of them began to appear.

The sinus has commenced to heal under appropriate surgical treatment, and between his seizures the patient

is not otherwise inconvenienced by the widespread nature of his lesion.

I should like to acknowledge my indebtedness to Sir Bernard Spilsbury for his kind assistance and advice, and my thanks are also due to Miss Vaughan of the Dunn Laboratories of the Surgical Unit of St. Bartholomew's Hospital for the photo-micrography of the sections.

## A CASE OF EXTENSIVE SOMATIC DISSEMINATION OF CYSTICERCUS CELLULOSAE IN MAN.

BY

MAJOR ROBERT PRIEST, M.B.CANTAB.,  
M.R.C.P.LOND., R.A.M.C.

As the opportunity seldom arises for observing in a living patient such large numbers and such a wide distribution of *Cysticercus cellulosae* throughout the body tissues, this case is, I think, worthy of record.

Pte. L., aged 24 years, had been a tramway worker in Lancashire before enlistment in April, 1920. After enlistment he had been able to carry out his full duties until October, 1925, when he was admitted to hospital for abdominal pain, vomiting, and fever, and it was then noted that his liver was enlarged to the extent of three fingerbreadths below the right costal margin. In November he had a similar attack, from which he recovered and was able to return to duty. So far as he was aware he had never passed any segments of tapeworm. On November 24th, twelve days after discharge from hospital, he had pain in the calf muscles which he noticed to be swollen. He could not walk far because of pain in the legs and shortness of breath. He reported sick again on November 28th, when it was noted that the muscular enlargement was not confined to the calf muscles, but that the muscles on contraction appeared nodular: certain nodules beneath the skin of the forehead and in the gastrocnemii were noted also. There was no oedema and the urine was normal. There was eosinophilia up to 4 per cent. On December 24th he had a "fit" during which the pulse was irregular and the rate rose to 120. When he came under my care on December 28th, 1925, he was pale and the face appeared puffy, but the two outstanding features were the chain of nodules visible on the forehead and the greatly enlarged, apparently well developed and powerful muscles.

The patient says he noticed the nodules first late in October or early in November. They are found in the subcutaneous tissues of the forehead, scalp, beneath the left eye, in the neck, and in the tissues of the cheek. They occur singly or in groups of two or three of varying sizes. When single they are ovoid, flattened ovoid, or spherical according to the amount of pressure exerted by the surrounding tissues. In size they range downwards from half an inch in the longest diameter. They are found in the aponeuroses of the abdomen, elbow-joints, thighs, and legs. In the muscles they can be felt singly, in groups, and in chains. One cyst is present in the left eye. They have not increased in size during observation. They may be described as fibro-cystic and are not and never have been painful. They are movable and not at all adherent to the skin.

Nearly all muscles are enlarged, especially those of the shoulder girdles, and on contraction the affected muscles present a nodular appearance. He gives the impression of being a powerful man of "Sandow" type development, but the muscle power is in fact very feeble. Enlargement is due to the presence of cysticerci and to the concomitant myositis. The muscles are tender. Vision at first was somewhat impaired in the left eye, but during the period of observation it deteriorated considerably. The heart does not appear to be enlarged, but the heart sounds are distant and not quite clear, and it seems probable that the heart also is invaded. In the central nervous system no localized lesion can be elicited, but during observation he has had five fits. They occur at any time, and on one occasion when he was asleep. They are accompanied by muscular twitching and jerkings, sometimes by cyanosis, sometimes pallor, and the pulse becomes irregular and the rate rises to 120. On one occasion the temperature rose to 99.2° F. He remains unconscious for four to five minutes, and this is followed by drowsiness and headache in the frontal region, especially over the left eye. He has no loss of sphincter control. His mental condition is not bright or quickly responsive, but his memory is good. The white cell count shows slight leucopenia, with a relative eosinophilia ranging from 12 to 6.5 per cent.

Vomiting occurred three times during the period of observation; it was not related to food; it occurred after a fit on one occasion, and at other times quite independently. No segments were seen in the vomit. The stools have been carefully searched daily for segments and ova, but without success up to date, even after the administration of anthelmintics. The urine at first contained traces of sugar, but since then has shown no abnormal constituents. The skin has never exhibited any evidence of urticaria.

On January 5th, to confirm my tentative diagnosis of generalized cysticercosis, two cysts were removed—one from the subcutaneous and one from muscle tissue. At the time of removal under local anaesthesia it was observed that the muscle (deltoid) was extensively invaded.

The following report on the removed cysts was received: "After removal of the scolex, they are found to be small oval cysts

showing at one point a darker area about the size of a pin's head. They contain a clear fluid and the dark spot proved to be the invaginated single scolex of the intermediate form of *Taenia solium*.

On January 6th the eyes were examined and the following report made: "The pupil reactions and all movements are

Diagram of left fundus. D=Optic disc, P=pigmentation, M=Macula, C=cyst, Cr=cysticercus.

normal. The left optic disc (D) is woolly at the edges, the blood vessels more engorged than usual. About a disc's diameter from the temporal side in a horizontal direction there is a small area of retinal depigmentation (P), a patch of choroiditis (C), fibrous bands with shallow opaque detachment of the retina leading downwards to a large subretinal cyst over which the vessels are stretched. The cyst shows a clear and well defined edge, is bluish in the outer portion, while the central area is hazy and opaque in which three or four dots can be seen. The cyst extends into the vitreous up to 5 D. The appearance presented is one of chorio-retinitis with a subretinal cyst due to the presence of a cysticercus."

As there is no evidence of the patient harbouring a *Taenia solium* now, and no history of his ever having acted as host to such, it is presumed that he must have ingested extraneous segments or ova. And as the digestion and dissemination of such is usually accompanied by constitutional disturbance, it is further presumed that the attacks of abdominal pain, vomiting, and fever were resultant to such dissemination, soon to be followed by painful muscles. In substantiation of this presumption is the fact that no nodules made their appearance prior to this illness in October. Up to the time of invaliding from the service he has received treatment by calcium salts and potassium iodide, and later by intravenous injections of novarsenobillon.

I am greatly indebted to Major Hood, R.A.M.C., for the pathological reports, to Captain Bell, R.A.M.C., for removing the cysts, and to Captain Kumar, I.M.S., for the ophthalmic examination

## British Medical Association.

### PROCEEDINGS OF SECTIONS AT THE ANNUAL MEETING, NOTTINGHAM, 1926.

#### SECTION OF MEDICAL SOCIOLOGY.

C. J. BOND, C.M.G., F.R.C.S., President.

#### PRESIDENT'S OPENING REMARKS.

THE PRESIDENT said he regarded it as a great privilege to preside over the Section of Medical Sociology for two reasons: first, because the subject of discussion—namely, "The effect of fatigue and monotony in industry," was a factor of increasing importance in the health and welfare of the industrial population; and secondly, because it was very desirable to enlist the interest of the medical profession (including medical officers of health and general practitioners) in the recent advances made in this field of industrial physiology and psychology.

This Section provided an excellent opportunity for bringing before the notice of their medical colleagues, as well as the public generally, the important work which was being carried on in industrial life by the Industrial Fatigue Research Board, the National Institute of Industrial Psychology, and by other societies and welfare workers interested in industrial hygiene.

A sound system of industrial psychology and physiology must be built on two principles: first, that every normal human being should strive to obtain some sense of satisfaction from energy expended and work done; failing such requirement, effort became reduced in volume or was diverted into other channels. The actual doing of the work itself must provide a fuller sense of satisfaction.

If industrial toil were less exhausting to mind and body, more stimulating, more health-giving, more interesting, then the growing demand for higher wages and shorter hours would be less insistent and greater benefit would be conferred on the worker. Consequently, a discussion of the factors in industrial life which tended to promote or to diminish the attainment of this sense of satisfaction must be of great importance. Among these factors the questions of monotony and fatigue had a very important aspect. The second principle was that the industrial problem was essentially an evolutionary one. It was largely a problem of adaptation to the industrial environment. If the worker was not fitted by nature, or had not been fitted by training, for his particular occupation, then he had not become adapted to his industrial environment. This opened up the important problem of vocational selection and vocational guidance in industry. In fact, it was not too much to say that the fitting of the work to the worker and the worker to his work was one of fundamental and growing importance, not only to the future of industry in our own country, but to the future of industry in the world.

### DISCUSSION ON THE PHYSICAL AND MENTAL EFFECTS OF MONOTONY IN MODERN INDUSTRY.

#### OPENING PAPER

BY

A. HUDSON DAVIES, B.A.,

National Institute of Industrial Psychology.

MONOTONY and fatigue are two aspects of a problem that affects the happiness and health of hundreds of thousands of workers in our civilization. It is not so easy, as mere separation on a notice of meeting would imply, to mark off two clearly defined fields of inquiry, and I think it is safe to say that in talking about monotony we shall find ourselves dealing simultaneously with some of the questions which will come up for discussion this afternoon. For although in our minds we can separate the more or less crude conceptions of fatigue and monotony, yet, when dealing with facts, and with situations in industry, it is often impossible to define clearly the responsibility due to either of these two factors, and frequently the remedies which we propose for one are directed to the relief of both. In work on these subjects we are to some extent handicapped by the long bridge from the laboratory to the factory. In other sciences data which at first lack sharpness respond to the refined treatments of the laboratory, but in dealing with human beings so many of the essential factors vary, when conclusions are sought in the midst of work, that in proportion to the extent by which we are forced to depart from objective controlled measurement, the possibilities of forming a clear opinion dwindle away.

The overlapping of work on fatigue and on monotony is explained by the fact that all evidence leads us to treat monotony as in some ways a special case of fatigue. To a limited extent we are justified in treating fatigue objectively. It has results which under suitable conditions can be expressed quantitatively. When work of any kind is done feelings of weariness, of disinclination for further work, and of desire for rest become prominent after a time. Muscular work causes diminished capacity for further activity, a decreasing rate of output (when the first slight stimulating effect of fatigue is past), an accumulation of waste products in the tissues, and finally increasing nervous inco-ordination. These effects can often be translated into terms of quantity. Physiological changes are not so obvious after mental work, but the general effects on rates of output and on accuracy of work are comparable with those following muscular activity.

Monotony is more elusive. It has no immediate physiological results distinguishable at present from those of fatigue—indeed, if we look on monotony as a special kind of fatigue this is not to be expected. It is not universal in its incidence under any given set of conditions, and it is not necessarily relieved by any particular remedy. In all

## EFFECTS OF MONOTONY IN MODERN INDUSTRY.

discussion of monotony it is important to remember that we are dealing with subjective factors, and that so long as the control which we can establish over them is liable to the complications—environment, individual differences, and momentary attitudes—which affect all human beings, our deductions are effective only in a general sense.

With this limitation it is possible to make broad deductions about the effects of fatigue and monotony in our functions, since to most of us fatigue and monotony do in fact connote more or less clear sets of ideas.

It seems possible to illustrate by a rather homely example the way in which monotony, or its synonym boredom—is separated from fatigue. At the end of a university boat race the two crews finish in a condition of fatigue which would horrify a factory inspector or an industrial psychologist. They recover rapidly, but as they pass the post the limits of exhaustion have been very nearly reached. During the race they have performed seven hundred repetitions of a movement that they have made probably thousands of times before. Yet no one would imagine that these men have been conscious of the monotony of their labour. They have had to preserve a complete exhaustion; they have had to remain keenly aware of many factors, such as alteration in the rate of striking or of the development of roll in the boat, to which no training can make reaction automatic. They are tired out, but they have not been bored.

These same men in practice for the race, however, have certainly suffered from the monotony of training. Besides physiological staleness there are periods in training where long spells of practice are accompanied by intolerable boredom, even when, owing to long use, hardly any fatigue accompanies the exercise, and the men land quite fresh in the physical sense.

We have variations over this whole range in industry. There are exhausting jobs—physically as well as mentally—which are not found to have that peculiar colour of monotony, while there are others so light that in the hours worked there can be no generally fatiguing effect, and yet the workers are keenly affected by monotony; if they persevere, they develop in time the symptoms of ordinary mental fatigue.

From the theoretical point of view the problem of monotony was first studied by Munsterberg in America. He defined monotony as a "subjective dislike of uniformity," and he put forward evidence that in repetition work the workers tended to defend themselves against this feeling by paying attention to minute differences between each repetition of the working cycle. By various laboratory tests, in which successive series of similar and different stimuli were applied to many subjects, he claimed to have distinguished between people in whom each experience in a uniform series facilitates a reaction to the succeeding ones, and those in whom the uniformity of the successive experiences has an inhibitory effect on the response. The former respond with less effort to each stimulus, the latter with an increasing effort as the series proceeds. He found evidence, by a general inquiry into the behaviour of all his subjects towards monotonous work, that those in whom this inhibitory effect was most marked were the ones who most disliked uniformity of work.

Although this theory was tentative, subsequent work has shown it to have elements of truth, and probably the best working conception of the mechanism behind feelings of monotony is the one which we owe to Professor Myers, who looks on monotony as a danger signal of the body there nervous exhaustion. In the structure of the body there are certain material limits—reserves of fuel, balances of acid and base, resistance of synapse and end-plate—which set a term to activity. These limits are always guarded by earlier nervous inhibition, which training, or the stress of some overwhelming necessity, can push nearer to the point of physiological exhaustion.

When a muscle is contracted voluntarily, impulses are sent up afferent fibres to the nerve centres, which tend to block further impulses to contraction. This is in the nature of a protective device, and in the typical ergograph tracing the growing effect of these impulses is seen in the successively smaller contractions, which dwindle finally to nothing. The muscle itself is not essentially less capable

of work, and the neuro-muscular apparatus is still efficient, for if the load is lightened effective contractions can again be obtained voluntarily. The blocking is therefore more central in origin, and the appearance of fatigue is directed only to one special set of conditions. Alter the conditions, and the inhibition disappears. The blocking is a safeguard, acting far in advance of the real limits of capacity for work.

By an analogy, which at all events is justified by introspective evidence, we may see in this dislike of uniformity a similar protection. There is competition continually going on for our attention; mental processes begin and cease—mostly involuntarily, though all of us develop powers of selection. While one process is occupying our attention others tend to be inhibited. The balance, however, is always shifting, and sooner or later one process gives way to another. When monotonous mental work is being done the competition of other processes is most severe. There comes a time when they break through into consciousness, and, by their own tendency to inhibit rival processes, make the continuance of the first process impossible. If it is necessary for any reason to keep these distractions out of the mind, feelings of monotony arise.

If we now examine a little more closely the behaviour of our boat crew under different circumstances it will be obvious that their boredom under training conditions did not depend ultimately either on uniformity of work or on its continuous repetition. The real difference between practice and racing was one of interest. Under the hectic stimulus of the race the crew has an aim, and everything is willingly subordinated to the object of reaching the post first. Fatigue, the anguish of driving on an exhausted body, matter nothing. During training, however, this object is remote. The daily routine creates an illusion of permanence; the race day is too far ahead for preparation to be stimulated by its prospect. There is a sameness about the long practice paddles, about the advice of the coach, which the crew finds infinitely depressing. There are times when nothing but a complete holiday will restore their poise. Uniformity and continuity of work, without the close incentive of competition, have temporarily destroyed interest, and the work is found more and more monotonous.

Now these features are increasingly obvious in the industrial situation, for there will be no going back from the development of invention and organization which has in the last century revolutionized production on the large scale. By dividing the operations of the work, by specializing the functions of the worker, production becomes more rapid and goods cheaper. At every point in the industrial process small jobs are being split off, to be performed by a new machine, or by a hand which, because it now does one operation instead of two, develops a skill which changing work would not permit. In the shoe industry the original work done by the village shoemaker is now divided between scores of operatives, using special knowledge and the skill of years on one fraction of an operation. The original working cycle is split up into many small work cycles, repeated with a minimum of variation hundreds, perhaps thousands, of times in the day. In some trades variety is demanded of the manufacturer, in others efforts are made further to standardize both operation and product, because the manufacturer believes that variation in either causes waste of skill and loss of productive power. With this tendency to division and to specialization the possibilities of interest and expression in work decline.

Repetition is, of course, not a new problem. Even the bootmaker made one boot after another; domestic work is often a rather uninspiring routine, and in hoeing a twenty-acre field a large number of very similar movements are made. But, through the logical extension of a process that began as soon as men ceased to provide all things for themselves, many more people are busy nowadays with repetition work, and the average length of the working cycle becomes progressively shorter. Two hundred years ago there was nobody living who was faced with the necessity of performing a two-second operation all day long for years on end. There are many in that position to-day, and to that extent we have a new situation.

It is not only that repetition destroys the possibility of interest, though any experience has only to be repeated often enough for further repetition to become irksome. Only while there are possibilities of new discriminations, of new reactions in ourselves, is it possible to attend with pleasure to the repetition. When once our favourite poem is sufficiently familiar to be quoted without shock in the morning newspaper leader something of its attraction has gone for us.

But the tendency of modern industry to deal with material as so many identical samples also removes the elements of interest from work. When the bootmaker finished his boot there was character and history in the making. Problems had been faced, particular difficulties overcome, which remained associated with the product. There was the possibility of an almost personal relation to the product. Because the modern worker deals only with one process, the range of difficulty is limited; in a short time there are no surprises, and his own contribution to a piece of work is overlaid at a later stage by the labours of other hands. All that is left is the necessity of passing a standard and of achieving output. Although derived interests do arise in connexion with work there is no longer the individual and personal response which was once possible. Work is becoming a price that is paid for leisure.

With increasing uniformity of material there is a steady pressure towards increasing continuity of work. The pictures which those unacquainted with industrial life draw of repetitive processes usually fail to allow for the fact that work is rarely continuous. Dr. Vernon of the Industrial Fatigue Research Board made an inquiry into the conditions of fifty apparently continuous jobs spread over boot and shoe making, tin canister making, laundry work, and packing operations. The working cycle varied from under one second up to as much as two minutes, with an average length of under four seconds. By making time studies of the work of various operatives, the number and duration of the breaks was analysed. Dr. Vernon examined only those jobs which seemed noticeably regular. Stops occurred for many reasons. Work had to be carried away or fetched; machines had to be stopped for cleaning or adjustment; there were waits when new supplies were not forthcoming. In the most continuous work—handkerchief-folding—there was an average of three breaks in the hour, totalling four and a half minutes. In other jobs there were breaks of as much as eleven minutes in the hour. Over the whole group workers who habitually sat at work got four breaks in the hour, which they spent walking or sitting, while standing workers got five breaks. There is, however, a tendency for these stoppages to be eliminated, although by affording opportunities for change of posture, for walking, and for conversation, they offer a welcome relief from the rhythmical inevitability of the work. Such unproductive time is from one point of view waste, if a skilled producing agent is performing small transport services, but it would be well to weigh against machine-like efficiency the human cost of increasing the continuity of work and the likely oppressiveness of its monotony in these circumstances. Output does not entirely depend on productive time.

Although on very uniform and very continuous repetitive work a higher proportion of workers will suffer from monotony than on more varied and interrupted work, there are still people who are not bored by work of this kind, and people who, even on the most varied work, maintain a steadily depressed attitude to life, and complain bitterly of monotony. It is safe to generalize and say that the actual temporal or material conditions of work do not make it monotonous. Monotony is a reaction, not to particular selected features of work, but to the whole circumstances of its performance. Its appearance is conditioned, not only by the industrial environment, but by personal relations of all kinds and by the circumstances of life in general for the worker who feels "fed up."

The theory of monotony as a warning symptom of central nervous exhaustion, consequent on the effort to maintain some mental process in the face of strong competing interests, is capable of being brought into close connexion with the operative in a factory. All industrial work in-

volves the maintenance of certain attitudes of mind—to the work itself, or to the people engaged in the work. The worker feeding a dial machine, or counting screws, is able to perform these operations with a minimum of attention after a time. It is not generally possible to concentrate on anything else, however, without detriment to the work, or even sometimes danger, and there are consequently voluntary restrictions on freedom of movement, necessities of behaviour, and inhibitions of normal impulses (such as looking up at a sudden noise), which have to be preserved. There is a perpetual holding of oneself in check. If there are no incentives powerful enough to strengthen the workers in these efforts, then sooner or later the special kind of fatigue which lies behind monotony will set in.

It is often extremely difficult to decide to what extent the monotony of work is oppressive. Suggestion always operates among groups of workers engaged on similar processes—a new-comer will suddenly open the eyes of a group to defects or conditions which had not affected them before. A worker genuinely affected by the dullness of a job sometimes destroys by her complaints the attitude of acceptance which others have managed to achieve. Recently, in a factory where the work involved was the counting of certain forms, and the sorting from them of a very few defective specimens, and where there was a periodic shifting of the workers from branch to branch, there was among new-comers a strong antipathy to the work, for lurid stories of the conditions in the counting office were circulated in the other offices of the firm. The new-comers were usually pleasantly surprised, for the compensations had not achieved the same publicity as the drawbacks. But among the old hands there was a good deal of complaint of the monotony of the work, in spite of short hours of work and very high pay. It was difficult to decide whether this tendency to complain of monotony arose because long continuance at the work reduced all to a state of boredom, or whether, as there seemed some reason to believe, suggestion from the few who really found the work intolerable—and however good the conditions, there are always some who hate such work—produced a general reaction against the work. There was a fixed quota of output, not unduly high, and many opportunities for breaks in the work, so that the conditions were not oppressive. There are likely to be many cases in industry where the oppressiveness of monotonous work will only be felt when suggestion has undermined resistance.

The mental effects of monotonous work vary from person to person. In nearly all repetition jobs in which monotony is felt opportunities are afforded for reverie. Probably there is no opportunity for thinking of a systematic kind, owing to the slight attention which must still be paid periodically or continuously to the work; but a vague, loose series of associations floats through the field of consciousness. To some workers there is an attraction in work which does not require close concentration. Others fall into an attitude of passive acceptance. The day slips by, and output piles up, while fragmentary pieces of experience are caught up, turned over for a few moments, and allowed to drift away again. There are workers to whom it had never occurred that objectively dull work was boring. If there are no standards of criticism towards aimless mental activity of this kind the worker is contented.

But increasing intelligence, and especially increasing education, have their effects. Among the girls on the counting process there were many to whom the limited scope of the work added to its burden. "Any fool could do this," they said, and they also in their work found opportunities of reverie. But their dreams were not altogether happy. Because at bottom tendencies were failing to find expression in the work, reverie became a means of escape, which is never adequate so long as the worker is conscious of the discrepancy between fancy and reality. These girls realized that their full powers were not being used. By way of reaction many of them said that though they once read books they had ceased to do so now. They seemed resentful that this should be so, and projected the responsibility on to the work. They felt, as one of them said, as if they were becoming "turnips," that they were not so intelligent as they used to be.

Reverie appeared by no means unpleasant, except in so

far as purposeless fantasy seemed undesirable. The girls felt an inertia, which seemed to be due, not so much to uniformity of work, as to the possibility of reshaping the world, which can be realized in fantasy. When the mind habitually turns away from externals the workers find relief in the easy play of ideas which goes on concurrently with work. It is not surprising if years spent in this way slowly destroy among the workers the wish to effect changes in themselves or in their environment. There is an easier path to a kind of half release which prevents efforts to a more positive satisfaction. Among these counters, who had all had secondary education, there were some who realized this vaguely, and added a slight feeling of guilt to the combination.

But there are more sinister effects of excessive reverie. Unless monotony is relieved it may be pushed, in limiting cases, to a point where there is a failure of inhibition, which allows the release of repressed unpleasant memories from the unconscious. This is liable to happen when central control is weakened by fatigue, and the peculiar circumstances of unlimited time for reverie and for unsystematized association, which monotonous work provides, set the stage for the development of neurosis. Even among normal people on monotonous work there are signs of maladjustment. Unreasonable fears are displayed of quite safe pieces of machinery, used thousands of times without accident; anxieties are more than usually obvious about output, about the opinions of fellow workers, about health; others admit to a feeling of being trapped, or "as if the day were leaving them behind"; while some girls on the counting process had a feeling that they were being watched, which was not justified by facts, even though some of their work was checked. The feelings of "guilt" also are in this class.

All of these tendencies may be the beginnings of psychopathic lesions. They do not occur in all people; they are always put forward apologetically as something rather stupid and not worth mentioning by those who experience them. In most cases, even after a long time at the work, the acquirement of interests outside the work and a generally healthy attitude to life offsets their beginnings. But in a few cases the symptoms develop to the point where psycho-therapeutic treatment becomes necessary.

Even when the stage of genuine psycho-neurotic breakdown has not been reached the presence of people with such tendencies has a noticeable effect on the atmosphere of the workshop. The internal dissatisfaction of a worker whose powers are not being used is sometimes not consciously seen at its true value, but spreads itself in resentment and criticism of the whole system. Such people grow irritable, the ordinary social amenities disappear, the perspective of affairs vanishes, and sometimes a tendency to aimless mischief arises. Thus there was a case where, out of detestation of monotonous work in a very poor environment, a crew of men handling fragile sheet material at a conveyor extracted an undoubted pleasure and relief from periodic destruction of some of the material. When conditions were improved the spoilage was reduced to insignificance. The protest of such workers is not always foolish, because it comes by way of reaction to the monotony of the work, and the mere fact of investigating their complaints adds something of interest to their work.

The only way in which physical effects can be attributed satisfactorily to monotonous work is by the comparison of groups of workers. This has so far not been done, though I believe an investigation on these lines is proceeding. The physical effects will not be connected with monotony, *prima facie*, for in those cases where monotony is felt to be most oppressive, the lesion that occurs will be functional and in the nature of a defence against continuance in the work. We have only to remember the case of miner's nystagmus to see that this is a possibility. It was found that the eye twitch which characterized this disease was functional in origin, and to some degree its occurrence was a method of unconscious self defence against the discomforts and dangers of the pit.

One of the obvious ways of preventing the development of boredom is to stop work. It was pointed out earlier that by increasing the continuity of work there was not necessarily a gain in output, and one of the tendencies

noticed in workers under these conditions is the taking of unofficial rests. Here again the counters before mentioned provide us with an example. Time study showed that, although counting was found dull and monotonous, it actually occupied less than two hours out of the six-hour day which was worked. There was a traditional, but unofficial, allowance of ten minutes away from work twice a day, whenever it was most required. But analysis revealed the fact that even with the slowest workers at least forty minutes of the day went in odd seconds and minutes of complete rest from work. With the fast workers even longer time was taken. Out of the total about two-thirds was taken in the afternoon spell. The feelings of monotony are most oppressive in the afternoon, and, as is usual when work consists of short repeated cycles, it was found that, although the actual speed of counting did not greatly fall off, increasing amounts of rest were being taken between repetitions towards the end of the day.

It has been thought also that the work curve can, in certain circumstances, provide evidence of monotony. This curve shows the rate of working at various times in the day, and in its usual form shows a rise from the start to a maximum at about the third hour of work, followed by a decline to the dinner hour. The afternoon curve rises rapidly at first, and then declines more or less sharply as the afternoon wears on.

Laboratory curves of work found to be monotonous by the subjects very often show a depression in the middle of the spell. The workers dash at the work at a pace which cannot last. Boredom causes a decline in speed, until, overestimating the time that they have been at work, a spurt begins because they anticipate the end of the spell. They finish strongly.

Wyatt has shown in continuous addition and computer work that this tendency to slow down in the middle of a spell is most clear in those people who find the monotony of the work most distasteful. It was found by Miss Burnett, in an experiment under conditions very close to those obtaining in industry, in which work was done with and without rest pauses, that the depressed curve was given preponderatingly by the more intelligent subjects—who were also the most bored—and especially on those days when, through the absence of rest pauses, the tendency to monotony would seem to be most marked.

From our inquiry it will be seen that any method of reducing the uniformity of work will be a step in the right direction, so long as the necessity of keeping a balance between too much change, with its irritating effect on piece workers and its depressing effect on output, and too little, with the danger of monotony, is realized. Any method which we can use to increase the interest or the incentive to work will be effective. Boredom is not felt, or at least has no chance of developing into serious nervous exhaustion, if the worker feels that, though the work is dull, it is worth doing. What makes it worth doing may be anything—from a high wage to a young man in the same factory. It may be pride in the organization, pride in one's own skill, or personal liking for the company the workshop affords. With a good factory atmosphere the plea of monotony is not put forward on work where other conditions would at once produce feelings of resentment and boredom.

In order to increase interest in work, short talks on the relation of each worker and his process to the general scheme have been suggested. Wherever it is possible some method of giving the worker an interest in output is desirable, and the change of outlook is often most marked when this is done. Miss Burnett's experiments were designed to illuminate this point among others. Her four subjects worked for two periods of three months, first on time rates and later on piece rates. The work was identical in both the periods. During the piece-rate period the girls worked harder, found much greater interest in the work, showed an almost complete absence of the monotony curve, and achieved increases of output which ranged from 9.3 to 17.9 per cent.

The value of rest pauses and of changes of work is also marked. The effect of breaking up the working period is to allow the prospect of stopping work to be an

incentive to continuing for the time being. Change of work, if that is possible, is more desirable than rest, for there comes a complete temporary breakaway from the attitude which has become wearisome. There may be opportunities for collecting together into a definite period various subsidiary operations, fetching and removing work, which would otherwise be done sporadically. Or it may be necessary to specialize the work of a group of people still further to get the required conditions. The National Institute of Industrial Psychology had a case where a group of girls were employed on a process which involved opening certain parcels, checking the contents, performing a punching operation on the contents, and remaking the parcels. The average time per parcel was thirteen minutes under ordinary conditions, but under supervision, not working at an exorbitant rate, two workers averaged eight minutes over a long period. Every one complained of monotony. There was much congestion and litter in the room, and between each parcel and the next a journey had to be made to the store shelves. By dividing up the work process, so that one team of girls did the preliminary opening of the parcels while the distribution and collection of work went to two inspecting and punching teams, not only was output increased by 10 per cent., even when rest pauses were inserted, but by having the three teams change functions at intervals there came a break to which all looked forward. Although each job involved more repetition than the old complete cycle, yet three repetition jobs done for an hour each proved permanently more interesting than the former longer and more varied process repeated less frequently. Here also we had an example of the environmental influence. As a result of the change in organization the room became tidier. There were fewer people, since with a 10 per cent. increase in output some could be moved to do other jobs. There was less moving about, and the possibility for the first time of developing rhythm or swing in the work. It became obvious that a part of the reaction against work in this room, which was so severe that only half-day shifts were operative, was due to the congested, irritating, and untidy conditions of work.

There is one more step which can be taken to reduce the incidence of monotony: there is still the possibility of selecting workers for the more dull and repetitive work by diagnostic tests. It has often been stated that intelligent people are more likely to suffer from monotony than the unintelligent, and it is quite true that, *a priori*, we should expect those who are most capable of dealing adequately with new and unexpected situations to suffer most in work which makes demands for no initiative. Miss Burnett found that of the four girls, the two most intelligent, as indicated by a simple "directions" test, found the work most monotonous and furnished the most objective evidence of monotony. But the stage has not yet come for the preparation of norms above which entry to a monotonous job will not be recommended. There must be time for the collection of more data, and valuable results may be forthcoming when the figures of labour turnover on repetitive jobs are analysed, with respect to intelligence, at the conclusion of the experiment on vocational guidance now being carried out by the National Institute of Industrial Psychology.

Specific tests of capacity to tolerate uniform work have been suggested. Except for Munsterberg's tests quoted earlier, which have not been much developed, most of these take the form of long uninteresting tasks in which the rate of output is measured continuously. There is some slight evidence that an erratic performance, with a widely varying rate of output from minute to minute, is an indication of the future liability of the subject to monotony. In addition to these special tests any method of selection which guides people into work for which innate dispositions and aptitudes fit them will, *pro tanto*, reduce the possibilities of disharmony, and so minimize the effects of monotony. Some of the worst sufferers are those who, through lack of dexterity or other disability, feel themselves on the verge of failure at their job, and, struggling against something which they do not realize as inevitable, grow disheartened and depressed.

I have tried in this paper to show how monotony depends on the interaction of many factors, of which perhaps the most important are personal ones. Since there is no doubt that many of the determining conditions are bound, under the present methods of production, to increase their influence over the general body of workers, it is important to recognize the results when we see them, and the ways in which monotony may be combated. If, finally, there is a gradation of interest, then suitable people must be steered into the most exacting work, for the general social welfare suffers while the wrong person fights against the uncongenial job. If the costs of improving monotonous work are economic, the losses through its continuance are not only in human values. One fears to preach to the converted, but it cannot be too strongly emphasized that mental attitudes are vital factors in production.

#### DISCUSSION.

Miss MAY SMITH (Industrial Fatigue Research Board) said that complaints and criticisms of monotony were usually made by highly educated people who went through a factory as observers, or in some instances as investigators. The besetting sin of the investigator was to put himself in the place of the worker, and then judge that work as it would affect him were he doing it. It was necessary to see the work as it really was to the worker. The word "monotony" meant one tone, and represented absence of stimulation; it was frequently attached to "repetition of movement." Repetitive movements must either be studied as such, in which case their problems belonged to the psychology of habit formation, or they must be put in their complete setting, which setting would include at least the repetition work, the varying amount done as the hours go on, the opinions of fellow workers and authorities about that work, physiological changes, emotional changes, and the collective life of the factory. Workers on one process frequently stigmatized as monotonous some other process, when to the observer there was nothing to choose between them. In itself, monotonous work could not be said to be detrimental to the health of the worker as such; as in so many other industrial problems, it was a question of relation—that is, of the effect of a given type of work on a given type of person. It was useless to criticize or attempt to assess a process regardless of the person who was to work at it. It was now comparatively easy to measure a person's general intelligence or neuro-muscular equipment; it was impossible to measure objectively the emotional make-up. A worker of average intelligence and skill engaged on routine work in an office or factory where the general atmosphere was dull, and where there was nobody in whom she took any interest or for whose approval she cared, might react in one of four ways: she might become a bad timekeeper, seize every opportunity for leaving the work, and become just as unsatisfactory as she could be without losing the job. She would probably be called "difficult," and be frequently in trouble. Secondly, in a person of similar intelligence and speed but of lower vitality boredom might quickly lead to sensations of tiredness, which in turn led to attention to some part of the body. That part which she was using might come into consciousness, and she would feel a pain and complain that her eyes ached, her head ached, that she had rheumatism, or that she suffered from indigestion which nobody could cure. It was rarely the happy and well placed people who had a sequence of sick leaves every year. The boredom acted as a negative agent, weakening resistance. Thirdly, the worker might carry on for years with gradually diminishing interest. Here the monotony was related to the general conditions of the work rather than to the actual repetition of movements. She would complain that the work got on her nerves; she would be irritable, and would probably have some form of "nervous breakdown." Breakdown was not infrequently equivalent to "fed up." Fourthly, the worker might get interested in the work, and might laugh if asked about its monotony; or she might accept it and compensate outside. Finally, there was the way out via the day-dream. This reaction was by no means universal, nor were its effects simple. Some people

## EFFECTS OF MONOTONY IN MODERN INDUSTRY.

could day-dream quite happily and carry on their monotonous work efficiently. The content of the day-dream could rarely be elicited, but it was usually of a compensatory type; it allowed of the expression of activities and emotions not normally expressed in reality. Others found that the day-dream interfered with their work; they tended to oscillate between the work, which did not occupy them fully, and the day-dream. Others, again, looked upon the day-dream as something to be opposed, and resisted it, wasting in the process valuable energy; they tended to have psycho-neurotic symptoms of a serious nature. Occasionally the day-dream, instead of being pleasant and controllable, became the master, and the subject became more and more self-centred and a victim of fantasy. In these cases the work was looked upon as a refuge from the unpleasant character of the day-dream.

Major T. KNOWLES (Supervisor of Messrs. Boots' Welfare Centre) said that the monotony of modern industrial processes was a subject of constant discussion, and visitors to some firms would remark of the work, "How monotonous! I couldn't do it; it would kill me." But what was monotony? Monotony was surely a question of individual preference, and it was impossible to generalize and say that such and such a thing was monotonous. If everyone found the same things monotonous, how monotonous every one would be. Was it possible to find interest in stamping boxes every day? His inquiries tended to show that the girls found much of interest in the work. No work was unskilled, and there was a definite pride in the way the work was done and in the speed of the work. Where girls were working in teams there was the desire to play a part in the group results, and where these results were posted the pride in individual skill and in the collective skill of the group was accentuated. In addition to the interest which the work itself created, there was the interest created by companionship and surroundings. It was said that there was deadening effect on the mental faculties of these workers, and a lack of opportunity for self-development. But leisure was the time for self-development, and Major Knowles would support any movement which removed the monotony from leisure and offered to the workers opportunities for development. He would claim that work need not necessarily provide the development, but it must provide the means for that development; and it was only by what had been called monotonous repetitive methods that this could be secured. Girls who had been for some years on repetitive work took their part in the mental recreations that were offered, and the non-vocational culture classes were made up largely of girls of this type. Finding it unnecessary to absorb their evenings at classes in shorthand, book-keeping, or that vague subject commercial practice, they were free to attend the housewifery, cookery, needlework, and leatherwork classes. To show the absence of detrimental results in repetitive work Major Knowles quoted the experience of an office department. In this particular office department there was a staff of two hundred girls, one-third of whom were engaged in adding machine work, the other two-thirds were employed in ordinary office work. The percentage of sickness amongst those engaged in repetitive work was about one-half of that for the rest. The girls on repetitive work were happy and healthy; they resented any effort to change their work; they were playing their part in the social, educational, and recreational work, and to arouse artificial discontent by constantly suggesting that the work was injurious was a futile thing to do.

The wise employer realized that his responsibility did not cease with the weekly pay envelope. Repetitive methods or any other methods would be harmful if the working conditions were not good. The employer should take every precaution, in time and motion study, to ensure pauses, and the provision of suitable apparatus to ensure safe and easy working; and welfare work in its medical, educational, and recreational aspects must co-operate.

The problem of monotony, said Major Knowles, was one of the many problems of industrial management, but they should be somewhat slow in their judgement on these problems. There was a new spirit in industry which would in time remove the suspicion and consequent opposition

that existed to-day. It was not by rules and regulations that they would succeed; statutory methods must fail. They must secure the atmosphere, and, above all, be moderate in their statements.

Miss SLOCOCK (Superintending Inspector of Factories) said that in endeavouring to get examples of what were generally considered the most monotonous occupations, or rather processes, she was at once confronted with the fact that in one sense there was no such thing as monotonous work. It was rather the reaction of certain human beings to certain work carried on under certain conditions, not necessarily repetitive work or work carried on for long spells. The question of character and temperament played such a large part that what appeared monotonous to one person might not prove in the least so to another. Inquiries showed that it was repetitive work of various kinds that was generally considered to be monotonous. It was probably the absence of creative aspect in any work that brought about the sensation of monotony. This aspect was well expressed by an old collar maker in the West of England who said: "Nowadays it is difficult to take any interest in one's work when one only does a small portion when you made the whole collar article. In the old days when you turned out a good one, you felt satisfied when you finished belongs to no one." It seemed impossible to get any very definite information as to the adverse effect of repetitive work on the mental and physical health of workers; but there were certain factors which had an important bearing on the subject. Thus it was customary to draft the new young worker on to the most monotonous job and to promote her as soon as opportunity offered to work requiring more intelligence. If the time spent on the monotonous work was not too long it was scarcely likely to affect the mental capacity of the worker and make her less adaptable to other work. Secondly, the shortened working day of eight to nine hours and the week of forty-seven or forty-eight hours had doubtless mitigated to a very large extent the fatigue which would result from longer hours of monotonous work. Under modern conditions and shorter hours the workers appeared to be brighter and more alert, even when performing monotonous jobs. Thirdly, automatic feeds were now eliminating much monotonous work. The tending of such a machine and keeping it supplied with material was a very much more interesting and less monotonous job than the continuous feeding of small parts or sheets into the machine. Fourthly, it was undoubtedly the environment in which the work was done rather than the work itself which affected the mental and physical condition of the workers. The mental atmosphere of the factory, if it was friendly and interesting, might soon compensate for lack of interest in the job. Constant nagging by an over-anxious foreman or forewoman and bad hygienic conditions, on the other hand, might soon create such a feeling of strain and worry that the most interesting work became irksome and burdensome, and the workers lost heart and health. Lastly, while scientific investigation into vocational selection, methods of work, the elimination of wasteful movements, the adoption of labour-saving appliances, and rest pauses and hours of work had helped to show how monotony could be counteracted, there was real need for warning as regards overspeeding. Work carried on at too high pressure was probably far more fatiguing and likely to affect the health adversely than work at the worker's own pace spread over a slightly longer period. Alternation of employment on unskilled monotonous work appeared to have an affection for their own particular job.

Miss K. DOWDING, of the Chiswick Polish Company, said that the inevitability of mechanical industry was now undisputed, but that highly organized methods brought new problems for the psychologist and physiologist, one of which was this new form of monotony. She used the term "new form of monotony" advisedly, for it was only reasonable to suppose that monotony and its ill effects had been present in connexion with the work ever since the

discovery that a subdivision of labour increased the sum total of work produced by any given number of men. Hand spinning, for instance, was now looked upon through very rosy glasses as one of the "old crafts," but to sit and spin alone would be indeed monotony to our modern girl.

Miss Dowding thought that there was very little real monotony felt by girls in well organized factories to-day. There was a type of girl who was constitutionally or emotionally unable to work either with machinery or on piece-work, because her natural rhythm was of a leisurely type. There were other girls who were truly mechanical and loved machinery, becoming peculiarly attached to their own particular machine, and others whose activities were excited and kept elated by piece-work. It was in greater care in the choosing and placing of the workers, and the more thoughtful provision and arrangement of their working environment, that the prevention of the mental and physical ill effects of repetitive production could be looked for. Correct placing in the first instance or transference in the early days determined frequently between the drifter and the contented artisan. Correct placing had its effects upon the whole group of workers. Nothing was easier than for a discontented worker to turn a pleasurable job into monotonous drudgery for a whole group of workers. This suggestibility of the workers made the whole problem of monotony so difficult. It was a most contagious complaint, and they should be extremely careful before they labelled monotony as an urgent industrial problem. Miss Dowding had been unable to collect evidence of any serious deleterious effects arising from repetition work, save in isolated cases of unsuitability which were capable of readjustment. In factories with good conditions it was easier to find instances of keen resentment and genuine distress at a suggested transfer. The whole question was largely one of the attitude of mind of the worker. It was the general feeling of being absorbed into some vast impersonal "thing" which was the foundation of the irksomeness of factory work—whether repetitive or otherwise. It was only by attacking this impersonality that the "dead level" of work could be altered.

In a paper which she was unable to read through absence, Professor WINIFRED CULLIS submitted that the word "monotony" now definitely carried with it more or less descriptive colour. To speak of a job as monotonous did not mean only that it was repetitive, made up of a series of efforts which might or might not in themselves be unpleasant, but that the general effect was an unpleasant one—in other words, it connoted an unpleasurable reaction to repetition. The discussion dealt with the repetition of actions which, though not sufficiently arduous to bring into play the type of protection associated with heavy muscular work, yet could produce a state of exhaustion quite as serious, or even more so. This kind of fatigue or boredom which came from repetitive work might be due to fatigue in certain nerve centres concerned in the performance of the action; or, as had been suggested by C. S. Myers, the fatigue might arise from the fact that the successful performance of a certain act necessitated the suppression of other actions not compatible with it. These inhibited mental processes became more and more difficult to suppress as fatigue from that inhibition set in. Investigation had shown that individual differences were very marked in reference to reaction to repetitive work. In the laboratory tests those subjects who gave the best showings on the findings of the intelligence tests were the most variable workers on the findings of the experimental tests. The introduction of rest pauses always had a beneficial effect; there was less fatigue, and the average output was increased quite definitely. Group working might counteract the particular desires or inclinations of an individual member of the group, and the fatigue of repetitive work might be lessened by paying special attention to the general arrangement of the work, and more particularly to the adjustment of the machine to the worker. In fact, the requirements were to make the times of work such as to be consistent both with the health of the worker and the prosperity of the industry; to introduce rest pauses under expert advice as to the period and duration, since these differ

from industry to industry; to give sufficient free time to the worker to undertake activities of a different kind; and to give the individual such an education as would enable him to make an enlightened and stimulating use of his spare time.

Dr. J. STEWART MACINTOSH (Hampstead) said that the issue was ultimately a biological one. The inhabitants of this country had passed successively through the hunting, pastoral, and agricultural stages, and the industrial era was at least as great a revolution as those which had preceded it. The simple traditions, whereby communities attached to the soil through many generations maintained their health, proved unserviceable to the huge, uprooted, and floating populations of the industrial districts. A new and more complex tradition must be devised by which physical and psychological adjustment to new conditions might be effected. They had to ask themselves the searching question whether they were eliminating the elements in their national composition which had made them great, or whether they were still going to maintain the quality of the British people by adapting the industrial machine more to the man and the man less to the machine.

Dr. J. JENKINS ROBB (Birmingham) agreed that it was most difficult to separate monotony from the question of fatigue. Both seemed to him interdependent and inter-related in their complexity. He feared that there was a distinct danger in the overemphasis of the question of psychology in industrial conditions, and in too much being claimed for it might lurk a factor akin to psycho-analysis. Psychology was not an exact science, and therefore its claims, so far as labour conditions were concerned, should be carefully watched. In reading the council's reports he felt they were in the most initiatory stages, that some of their tables referred to very small groups, the smallness of the group making conclusions unsafe. Judgement and conclusive evidence must be based on large experience properly correlated. Monotony was not so apparent to the less educated, an argument against such labour, though thoughtful workers, he found, resented it. In his opinion much of what was termed neurasthenia was so caused. He would like to know the relation of monotony to sickness benefit, for in looking into this question in a large group of organized workers in a friendly society's report, he found that in this section sickness was now costing more, and last year showed that income from sick rates did not meet expenditure. Taylor's motion study had for its object increase of production, and even Taylor's figures showed that while production went up to a great extent, wages made a comparatively small advance, and the percentage of rejected was high. So the present-day worker was suspicious of any system or plan which meant observations with a stop-watch in hand so that he might be speeded up; for to him it meant, as a rule, a relative drop in wages; it bred discontent; and discontent in work was twin brother to monotony.

Dr. J. LOCKHART (Nottingham) objected to the frequent use of the term "neurasthenia" in certificates. When the patient was only vaguely ill the panel doctor, whose certificate alone was valid for benefit, had to put something down. He used the word "neurasthenia"; and the label, once applied, took months to unstick. Medicine was a clinical problem; if industrial medicine was to be any good it involved co-operation with the doctor outside. Dr. Lockhart desired that the Ministry of Health should make this co-operation official.

Dr. CHRISTINE MURRELL (London) believed that the element of compulsion produced monotony. She hoped that the development of machinery would in time remove monotony to the machine. The testing of vocational capacity was of the utmost importance.

Dr. C. FORBES (Aberdeen) said that monotony appeared, at the present time, to be an essential part of industry. It might be anticipated that the progress of invention would gradually replace by mechanical devices the more monotonous processes now carried on by human beings.

In the meantime welfare work was to be encouraged, aiming as it did at neutralizing as far as possible the effects of monotony in work. While many workers employed in monotonous work did not find it irksome some undoubtedly did, and, either on account of intelligence, education, or of temperament, were broken in health and happiness by routine. These should be eliminated by vocational tests and given more varied work to do.

Sir THOMAS LEGGE (Home Office, Whitehall) thought that welfare work would gradually bring back some portion of the interest in work that existed in the mediaeval guilds. In the guilds there was comity between employer and employed; the sick were cared for, good work was important, and pride was taken in the work. Trade unions and employers should have the same aims nowadays. Competition, which was absent in the guilds, was producing monotony, though complaints of monotony had not been brought before him much by the workers themselves. There were, indeed, many more urgent conditions that required to be got rid of before monotony was tackled.

Dr. BRACKENBURY (London) said that Sir Thomas Legge was thinking more of the physical effects of monotony; they should think also of the mental effects. It was curious that nearly all the speakers had spoken on female mentality. Was there not also a mentality of men? He would like to see communal pride, as well as individual, in the products of labour—pride in the finished products in which the workers had taken part. There should also be artistic pride in the products, and the development of this would be helped by the nature of the surroundings, an artistic environment for the worker. And, most important of all, work must not be separated from the rest of life. A proper attitude towards life in general should be instilled into the minds of the worker.

Dr. H. S. BEADLES (Romford) said that he, like others, had started as an idealist; but with thirty years' inside experience of many of the large factories of most types of industry, he wished to warn his hearers against too much interference with the life of the worker, particularly outside the factory. Having been asked by the Home Office to help in the formation of statistical records, he did not feel in a position to do so; and he noted that statistics were quoted in percentages on the result of as few as three cases investigated. Welfare departments had been of great help to the worker inside the factory provided they had been in suitable hands, but some of the superintendents of these were following the workers into their own homes; the interference involved in this was seriously resented by many of the employees.

## DISCUSSION ON THE PHYSICAL AND MENTAL EFFECTS OF FATIGUE IN MODERN INDUSTRY.

### OPENING PAPERS.

I.—W. LIONEL HICHENS,

Chairman of Cammell, Laird and Co.

I HAVE no pretension to expert knowledge on the subject of industrial fatigue, and I cannot even claim that degree of practical knowledge which comes from daily contact with workshop practice. But I can claim to be keenly interested in the subject, since I have been a member of the Industrial Fatigue Research Board from its early days, and have followed its activities closely.

This has been called the age of science, and the importance of research and the application of science to industry is widely recognized. We realize the importance of an exhaustive research into the properties of coal or of iron and steel, but we are not perhaps so fully alive to the need of research as applied to the human factor in industry. And yet the human factor transcends all others in importance. It is not merely that we want industrial workers to be healthy; it is not merely that we want them to be wealthy—and in spite of all that is said to the contrary we do want that; we want them also to be wise and con-

tented. And contentment must be based on the knowledge that their health and well-being are cared for.

"Industrial fatigue" is perhaps an unfortunate term, because it is both too wide and too narrow. It is too wide because it seems to imply that there are certain trades in this country which demand such strenuous physical exertion as to affect the bodily or mental health of the worker. Under the modern conditions of an eight hours day, and given good health and good training, I do not believe that this is the case. I do not deny, of course, that many forms of industrial work are physically exhausting if pursued too strenuously or for too long spells, but on the whole legislative safeguards are adequate, combined with the natural human instinct of self-preservation and the experience of ages, to cause all classes of workers to adjust their output so as to prevent physical or mental injury. During the early days of the late war a heavy demand was made on the workers in certain industries, and they responded magnificently. But it was found that after a time the workers were unable to maintain the pressure, and that a better output resulted from reduced hours of work. The instinct of self-preservation asserted itself before the health of the workers was seriously undermined. At the same time, it is obvious that some forms of work are more fatiguing than others, and they deserve study in order that the point at which fatigue begins may be postponed as far as possible, and in order that the well-being and efficiency of workers thus engaged may be improved. Again, it is undoubtedly true that fatigue—even where its direct consequences are not injurious—pre-disposes its subject to certain diseases. Hence I am convinced that the work carried out by the Industrial Fatigue Research Board is of great value, and deserves the widest public support.

I propose to indicate broadly some of the directions in which the study of the problem of industrial fatigue may be pursued with advantage. In the first place, it is obviously desirable to eliminate all unnecessary physical effort, and as far as possible to substitute machinery for hand labour. This is primarily, of course, a problem for the engineer, and it is difficult to overrate its importance. If the objective of industry is to be, as it should be, to pay high wages, this can only be done as the result of high productivity, and improved mechanical devices must necessarily play a principal part in the attainment of this end. But while, as I have said, the substitution of machinery for hand labour is primarily the work of the engineer, research workers engaged on the problem of industrial fatigue have also their part to play in studying the design of machinery from the point of view of the comfort and physical convenience of the workers. This is one of the problems that are now engaging the attention of the Industrial Fatigue Research Board, and the inquiry is likely to be fruitful in results.

Time and motion study is another important aspect of the industrial fatigue problem. Most people are familiar with the work that was initiated by Mr. Taylor and Mr. Gilbreth in America. We know how, as the result of a brilliant piece of investigation, Mr. Gilbreth reduced the motions involved in bricklaying from eighteen to five, and increased the number of bricks laid per man per hour from 120 to 350. We are familiar with Mr. Taylor's studies in regard to the rate of loading pig-iron. We know, too, that "scientific management" met with determined opposition in America when it was first started. But it is important to remember also that this opposition has died down, and that American trade unions are in general strong supporters of scientific management. Many of them, in fact, have their own efficiency engineers, whose task it is to educate backward managers, as well as workers, in efficient methods. And herein, I think, lies the main difference between America and this country. We are in no way behindhand in scientific research, but I fear that the attitude of trade unions to scientific management is less friendly here than in America, although I believe that the Industrial Fatigue Research Board, of which the chairman is a prominent Labour member of Parliament, has done much to break down earlier suspicions. But here is one of the ways in which employers and workers might with great advantage co-operate more closely.

It has been established that a scientific study of the motions in industrial operations has led to the elimination of much unnecessary effort. The study of posture, change of posture—the method of carrying weights, for example—have an important bearing on the well-being of the worker and contribute to the lessening of fatigue as well as the increase of efficiency. In this work the Board has received valuable assistance from the National Institute of Industrial Psychology. An important aspect of motion study which may lead to valuable results is the study of classes of work that involve the excessive use of certain muscles, and set up a local fatigue which may result in illness. Telegraphist's cramp is a case in point. It may be possible sometimes to bring other muscles into play and thus relieve the strain, or steps may be taken to improve the circulation through other muscles, since it has been established that recovery from severe fatigue in a sharply localized group of muscles may occur by the removal of the fatigue product—lactic acid—through other parts of the body.

Another subject of considerable importance to those interested in the problem of industrial fatigue is that of rest pauses. What is the optimum spell from the point of view of efficiency and the well-being of the worker in any given trade? Dr. Vernon and Mr. Wyatt have collected important evidence which tends to prove that wherever spells of work are four and a half hours or longer the judicious use of rest pauses of from five to ten minutes is beneficial. Hours of labour are to-day a subject of political controversy rather than of scientific inquiry; this is to be regretted, because the problem will never be solved by cries of "slave-driver" and counter-cries of "slacker." Those of us—and they are many—who believe that employer and employed alike should give to the community the best work of which they are capable, consistently with physical and mental well-being, will probably agree that more time should be given to the scientific study of the problem, believing that along these lines alone can be found a solution which safeguards both the welfare of the worker and the well-being of the community.

I have mentioned certain subjects which appear to have a direct bearing on the problem of industrial fatigue, but there are many others which ought not to be ignored. One of the most important is the effect of temperature upon output. Dr. Vernon has shown that in heavy work, especially when it involves exposure to high temperatures, output undergoes a consistent seasonal variation, being with very few exceptions greatest in winter, least in summer, and intermediate between the two in spring and autumn. Again, there is evidence to show that the capacity of workers in hot mines is some 30 per cent. less than that of workers in cool mines. This, perhaps, goes to prove that the natural protective instinct is at work to prevent workers from putting an undue physical strain on themselves in unfavourable conditions. But it also shows the importance of studying problems of ventilation and atmospheric conditions with a view to minimizing fatigue. It is also important that the incidence of sickness in the heavy trades should be more closely studied. Dr. Vernon has shown that in the iron and steel trade men on the heaviest work experience the most sickness—mostly rheumatism and respiratory diseases. Probably this is due to the greater risk of chills, and it might largely be prevented by proper precautions.

Other subjects which might be mentioned are the proper lighting of factories, the provision of baths in certain trades, liability to accidents, vocational selection and guidance, all of which have a bearing on the problem of industrial fatigue; but I think I have gone far enough for my purpose. My object has been to try to show that there are many problems connected with fatigue which repay study. There is still much to be done to improve the conditions under which industrial work is carried out, and it is of national importance that the operations of the Industrial Fatigue Research Board should be encouraged, not merely by the Government, but by employers and workers alike. In some respects the Board is still groping in the dark; in some cases it is only able to carry out laboratory experiments because the necessary co-operation of the industries concerned is not yet forthcoming so as to enable

large-scale experiments to be made. But important results have already been secured, and, since the effect of its work is cumulative, I feel confident that, if it receives the support it deserves, the Board will render services of lasting importance to the industries of this country.

## II.—H. M. VERNON, M.D., B.Ch.,

Investigator for the Industrial Fatigue Research Board.

THE opener of this discussion has dealt with the physical effects of fatigue in general terms, so it may be worth while to bring to your notice some specific instances of fatigue effects which have been investigated during the last few years. Fatigue affects both the health and the efficiency of the workers, but as it is much easier to measure its influence on efficiency than on health, I will first describe some of the observations I have made on fatigue in relation to working capacity. My first instance relates to the tin-plate trade. In the manufacture of tin plates, "bars" or plates of steel, usually about 20 inches long by 9 inches wide and weighing 20 to 40 lb., are heated to a bright red heat in a furnace. The furnaceman pulls them out, one by one, by means of long tongs, and pushes them across the floor to the roller man, who picks them up with short tongs and passes them between heavy revolving iron rolls. This flattens them out to about three times their previous size, and then they are taken in hand by the doubler, who folds each sheet over, and presses down the bend by means of his foot (on which he wears a special boot). The bend is further flattened by means of a mechanical squeezer, and then the sheet of metal is flung back to the furnaceman, who returns it to the furnace for a further heating. During the whole of these operations the sheets of steel remain red-hot, so the men have to endure exposure to a very large amount of radiant heat, as well as suffer the fatigue of lifting the heavy sheets of metal. They stream with perspiration, in spite of their wearing short shirts, open at the waist and neck. As the result of observations collected at five factories over a period of several years I found that the output of the men was at a maximum in January, the coldest month of the year, and fell steadily till it reached a minimum in July and August. Then it rose again steadily as colder weather set in. However, this seasonal variation was by no means the same at all the factories. Many of the factories have artificial systems of ventilation in which cool air is blown down on the heads of the men, and at the best ventilated factory I came across the summer output of the men was only 3 per cent. less than the winter output. At another factory, where the artificial ventilation was moderately good, it was 6 per cent. less, while at two other factories, where there was no artificial ventilation at all, it was 11 to 13 per cent. less. For reasons which I will not go into now, I concluded that the installation of a thoroughly efficient system of ventilation in an unventilated factory would increase the average output for the whole year by 12 per cent. or more.

I have described these observations on tin-plate millmen in some little detail as the conclusions hold, in greater or less degree, for many other classes of men employed in the iron and steel trade. Take the steel melters who produce steel on open hearth furnaces. When these men have tapped their furnaces, and run off the molten steel, amounting in some instances to 100 tons, they sometimes have to mend the floor of the furnace. They do this whilst it is still white-hot, and as they approach within a few feet of the open furnace doors the work is excessively hot and exhausting. I found that the output from the steel furnaces was distinctly less in the summer than in the winter, and in one steel works where the ventilation was poor the summer output was 11 per cent. less. In other works, where the ventilation was good, the reduction of output was much smaller. Similar seasonal variations were observed among the men working at the rolling mills and the blast furnaces, and the men engaged in puddling wrought iron; so it may be laid down as a general rule that the more strenuous the work, and the less favourable the conditions under which it is performed, the more does the output tend to fall off during hot weather, in consequence of the extra fatigue induced.

Confirmatory evidence of the adverse effect of high temperatures has recently been obtained by Mr. Bedford and myself in coal mines. It is almost impossible to compare the output of different miners, as the case with which they get the coal varies so much from day to day and from place to place, so we adopted another method of measuring their physical efficiency. This depends on the fact that no man, when engaged in heavy work, is able to work continuously. Inevitably he rests occasionally, so we kept individual coal hewers under observation for a period of one and a half to two hours each, and noted down the number and duration of their rests from work. Observations were made on 138 men in all, and we found that whilst the men working under the best atmospheric conditions, when the wet-bulb temperature was 66° F. and the cooling power (as estimated by wet kata-thermometer) was 15 to 18, rested for seven minutes an hour on the average, those working under more adverse conditions took longer rests, and the men working under the most adverse conditions of all, when the wet-bulb temperature was 79° and the wet kata cooling power was 6.4, rested for twenty-two minutes an hour. The atmospheric conditions influenced the speed of work as well as the rest pauses, for we found that whilst, under the best conditions, the men took eight minutes to fill each 10 cwt. tub with coal, they took 9.6 minutes, or 20 per cent. longer, to fill them under the most adverse conditions. From these data we were able to calculate that the efficiency of the men working under the most adverse conditions was 41 per cent. less than that of the men working under the best conditions, whilst with intermediate conditions intermediate reductions of efficiency were observed. The men appeared to be particularly susceptible to air movement, and a moderate improvement of ventilation produced a considerable increase of output, so we seem justified in concluding that all men engaged in heavy work which causes them to perspire freely are considerably benefited by good ventilation.

In spite of the adverse effect of poor atmospheric conditions on efficiency, it does not necessarily follow that the health of the men is affected. In order to obtain direct information on the subject Mr. Rusher and I obtained access to the National Health Insurance cards of 22,000 iron and steel workers, and determined the time lost from sickness over a six-year period. We found that the hotter and heavier the work of the men the greater their loss of time from sickness; for the steel melters, to whom I have already referred, lost 23 per cent. more time than the average, whilst the puddlers lost 20 per cent. more, and the tin-plate millmen 12 per cent. more. On the other hand, the iron and steel men who worked at ordinary temperatures lost 9 per cent. less time than the average. The excess of sickness in the men exposed to high temperatures related chiefly to rheumatism and respiratory diseases. This sickness was largely due to the men sitting about, in the intervals of their work, in clothes which were damp from perspiration, and we concluded that, generally speaking, physical fatigue influenced health indirectly rather than directly. This conclusion was supported by the mortality data, for the various groups of iron and steel workers investigated showed a lower mortality than the general population (of all males, occupied and retired), with one exception. This related to the steel melters on open hearth furnaces. Their mortality was 20 per cent. greater than the average of all males, and 26 per cent. above the average of our whole group of iron and steel workers. We concluded that the excess of sickness and mortality in the steel melters might, in some degree, be the direct effect of the work of furnace mending, as this is far more exhausting than any other kind of industrial work known to us.

Apart from its influence on general health, physical fatigue undoubtedly has an influence on accident liability. Striking instances of this fact came to my notice during the war. At a large fuse factory the hours were at first twelve a day and seventy-five a week, but subsequently they were reduced to ten a day and sixty-four a half a week. This reduction of hours had no effect on the accident frequency of the men, but that of the women fell to about one-third of its previous value, as it so greatly relieved their physical fatigue. Again, Mrs. Osborne and I found

that accident frequency was much influenced by atmospheric conditions, such as temperature. We found that the minor accidents incurred fell to a minimum at a factory temperature of 67°, whilst at a temperature of 77° they were 39 per cent. more numerous in the men. Probably this rise was due, at least in part, to the physical fatigue of the men, though it acted indirectly rather than directly by diminishing their attention and alertness.

Evidence bearing on accident liability in relation to the fatigue of miners was obtained by Davies at the Morro Velho gold mine, Brazil. In the deepest workings of this mine, some 6,000 feet below the surface, the wet-bulb temperature reached the almost insupportable figure of 89° F. A cooling plant was introduced, which cooled the intake air to 43°, and the wet-bulb temperature in the deepest workings to 80°, and it was found that whilst in the sixteen months previous to the installation of the plant there were twenty fatal accidents, they were reduced to six in the subsequent sixteen months. Again, Mr. Bedford and I found that the accident liability of the miners studied by us was distinctly influenced by the atmospheric conditions. We obtained data relating to 3,000 miners for a six-year period, and we found that the accident rate of the men working at the coal face of the deeper and hotter seam in a mine (with a wet-bulb temperature of 74°) was 52 per cent. greater than that of the men in the upper and cooler seam (with a wet-bulb temperature of 62°), in spite of the fact that the physical conditions, such as the soundness of the roof, were better in the deeper seam than in the upper one.

It is desirable that further evidence on the subject be obtained before a definite conclusion is arrived at, but in the light of the information so far available we are justified in assuming that improvements in the atmospheric conditions under which the miners work would have an appreciable effect in reducing the terrible accident mortality to which they are subject.

To sum up, it appears that whilst the physical fatigue induced by heavy industrial work is apt to reduce health and efficiency and to increase accident liability, much can be done to diminish these adverse effects by improving the atmospheric conditions under which the work is carried on.

#### DISCUSSION.

Dr. J. STEWART MACKINTOSH (Hampstead) said that fatigue phenomena might be excited by agents other than excessive muscular effort, aggravated or not by an ill devised environment. Toxic and psychic influences were also potent determinants of physical fatigue. Toxic causes included bad or unsuitable food (with its disturbance of the digestive and other systems of the body), septic foci, endocrine disorders, etc. Again, anything provocative of mental conflict, such as trouble in the home or the young man courting another girl, frequently resulted in diminished output or carelessness through a portion of the total available energy of the individual being consumed by intrapsychic tension. Fussy or inquisitive interference by so-called "welfare workers" was to be deprecated; but the hinterland as well as the foreground of the industrial field must be surveyed. Much good work could be, and some had already been, done in this regard by persons possessing the requisite tact and knowledge.

## Memoranda: MEDICAL, SURGICAL, OBSTETRICAL.

### SCOLIOSIS DUE TO UNILATERAL MUSCLE SPASM.

THE following case is of some interest and sufficiently rare to warrant publication.

In March, 1924, a girl, aged 15, had what appeared to be an attack of lumbago: it became more acute until after about ten days she developed a bilateral sciatica. Pain was worse on walking and worse off somewhat during the day. In spite of salicylates, and later complete rest in bed, pain and stiffness increased. Diathermy and, later, change of air gave no benefit. She then went to Bath, where ionization, baths, and hot packs were tried, at first without effect, but later the sciatica ceased to be continuous and was only brought on by movement, and the back became temporarily less stiff after the baths. At this time

she developed intermittent spasm, sometimes of the middle portion of the right erector spinae and sometimes of the right abdominal muscles, bending her either directly to the right or forwards and to the right. The spasms increased in violence and were only loosened by the hot baths; lateral curvature and pelvic tilting increased till she could only stand on one leg, and kneeling was the only tolerable posture one whole night being spent in this position. The spasm generally came on during sleep and woke her up. Massage and exercises made matters worse. A skiagram taken at this time was negative. She returned home and remained in bed with daily massage, but the lateral spasm and consequent scoliosis increased. Hysteria was diagnosed by one physician, on what would appear somewhat inadequate grounds, and an osteopath manipulated the spine, but no benefit accrued. By August, 1924, the spasms were so acute that sleep could only be had in short spells. At the suggestion of a neurologist intramuscular injections were made under an anaesthetic; there was no immediate effect, but in September the spasms decreased in frequency and violence, the pain diminished and she could sleep better, and even walk occasionally for some distance, although the abdominal muscle spasm attacked her when she became tired. However, the erector spinae spasm and scoliosis increased with occasional exacerbations, generally relieved by recumbency. The condition remained stationary through the winter.

In February, 1925, she was seen by Sir Robert Jones and myself. Pain and acute spasm were intermittent, but the right erector spinae between the mid-dorsal and mid-lumbar regions was in continuous spasm and stood out as a hard mass, and the spine was correspondingly held convex to the left, with pelvic tilting. There was no permanent abdominal spasm. She appeared to be a most intelligent and healthy girl with no symptoms of hysteria. We came to the conclusion that the trouble was caused by adhesions around the spine and nerve exits, and accordingly mobilized the spine fully under an anaesthetic. Many adhesions were felt and heard to give way. From that time onwards she has been under my care.

The day after the mobilization the spasm had disappeared and only occasional suggestions of it remained for about a month. Exercises were prescribed and have been continued, and I have seen her three or four times during the year ending April, 1926, and she has remained perfectly well and with no scoliosis.

This case never suggested a diagnosis of hysteria and was entirely unlike the hysterical curvatures and tilted pelvis with which we are all familiar. It was obvious that there was a definite irritative lesion of the nerves supplying the affected muscles. Personally, I had seen one similar case, much less severe, and Sir Robert Jones tells me that he has seen three or four such cases in the course of his experience, but none more marked than this.

London, W.

#### RECOVERY AFTER INTRACARDIAC INJECTION OF ETHER.

In view of the cases recently described, the following, which have lately occurred in my practice, may be of interest.

*Case 1.*—An adult male on whom I was proposing to operate for inguinal hernia gave no history of previous heart trouble, and the heart sounds appeared normal. Just as I was about to make the primary incision with the patient under open ether he stopped breathing, no pulse could be felt at the wrist and no impulse at the apex. Artificial respiration was commenced and both strychnine and ether given hypodermically, but, as was to be expected in the absence of circulation, these were ineffective. One cubic centimetre of ether was injected directly into the left ventricle, and almost immediately the pulse became palpable, breathing began again, and I was able to do the radical operation. The patient made an uninterrupted recovery and suffered no after-effects.

*Case 2.*—I was sent for by the midwife to a woman in labour (sixth confinement), and found a shoulder presentation with one hand in the vagina. There was a history of previous "heart weakness," and she had a systolic murmur heard at all orifices. I gave chloroform while my colleague proceeded to turn and pull down a leg. She became rather grey, so I went cautiously with the anaesthetic. The after-coming head jammed at the outlet, and during manipulations to release this the patient stopped breathing. I could feel no pulse and no apex beat. Artificial respiration and subcutaneous medication were again tried, but were ineffective, so that 1 c.cm. of ether was injected directly into the left ventricle. I had my finger on the radial artery and the return of a palpable pulse was very striking. The first beat was felt after perhaps ten seconds, the second about five or six seconds later, the third after about three seconds more, and thereafter the normal rhythm was rapidly established. The child was extracted and was, of course, dead, but the mother made an uninterrupted recovery and suffered no after-effects.

Whether in these two cases the heart actually stopped or went into fibrillation I cannot say. But the response to intracardiac ether was dramatic and most gratifying to all concerned.

Wrotham, Kent.

## Rebuelus.

### ELLIS ISLAND.

THE title of Dr. BERTHA M. BOODY's very interesting book, *A Psychological Study of Immigrant Children at Ellis Island*,<sup>1</sup> is somewhat misleading; her experimental study occupies little more than a third of the pages, and, although suggestive, particularly with regard to the possibilities of testing intelligence when examiner and examinee have no language in common, would be too slight for separate publication. That her work is thoroughly worthy of book form is due to the fact that it contains a readable account of the history and present administration of immigration laws in the United States of America. Fears that the United States might become the dumping-ground of undesirable aliens are not new. In 1819 these words were used by the committee of a New York society: "As to the immigrants from foreign countries, the managers are compelled to speak of them in the language of astonishment and apprehension. Through this inlet pauperism threatens us with the most overwhelming consequences." Similar apprehensions were voiced during the ensuing fifty-three years, but it was not until 1882 that any Federal regulation was attempted, when lunatics and idiots were legally excluded. After 1891, when deportation of aliens admitted contrary to law was ordered, control became tighter. In 1907 feeble-minded persons were debarred, in 1917 all aliens over 16 unable to read the English or some other language were excluded, and by the Act of May 19th, 1921, immigration was restricted to a quota of 3 per cent. per annum of the number of the particular nationality recorded in the census of 1910. Finally, in May, 1924, the quota was changed to 2 per cent. of the foreign-born population shown at the census of 1890. After July 1st, 1927, the annual quota is to be a number bearing the same ratio to 150,000 that the number of inhabitants of the United States at the census of 1920 having that national origin bears to the whole population. Dr. Boody says that the result will be the reduction of the number of immigrants from 360,000 to about 150,000, but, unless the term "national origin" is to be understood in some very peculiar sense, we should suppose that the annual number would be considerably short of 150,000. This at least is quite clear—namely, that immigration will soon be a relatively unimportant source of population increase in the United States. Already there is a great difference between the million and a quarter of the "peak" year of 1907 and the net influx of less than half a million in 1923.

The object of this legislation and the administrative measures based upon it is not only to ensure that those admitted are physically sound, but, in the words of one authoritative body, to ensure that "no alien should be admitted who has not an intellectual capacity superior to the American average." Since the would-be immigrants speak twenty different tongues, and include children who cannot read or write, psychological tests alone present a formidable problem. It is not easy to devise a rapidly applicable test of intelligence success under which is wholly independent of acquired knowledge, and the language difficulty greatly complicates the task. When, in addition to all this, it is desired to take account both of eugenic factors and the mysterious attributes of "race," one realizes how difficult is the problem which American administrators and men of science are attempting to solve. The scientific and administrative machinery so far developed functions on its largest scale in Ellis Island, a name which neither the British Ambassador's report of three years ago nor recent press reports have favourably recommended to the home-keeping Englishman. The fourth chapter of Dr. Boody's book, which describes the present procedure, is sure to be read with particular interest. At the outset one perceives that the American Government has at least overcome one of the prime difficulties of both research and administration—that of

<sup>1</sup> *A Psychological Study of Immigrant Children at Ellis Island*. By Bertha M. Boody, Ph.D. Mental Measurement Monograph, Serial No. 1. Baltimore: The Williams and Wilkins Company; London: Baillière, Tindall and Cox. 1925. (Med. 8vo, pp. 163. 18s. net.)

expense. It seems that Ellis Island, far from being a source of expense, returns a handsome profit. In the year ending June 30th, 1923, the net profit of the island was rather more than 1,800,000 dollars. If the American Government had already devised a method of preventing any but the physically and intellectually elect from entering its territory, and of securing an annual bonus of more than £350,000 as well, our reverence for the great republic would be, if possible, increased. It does not, however, appear that Ellis Island quite rises to these heights. The actual psychological testing, as described by Dr. Boody (we do not, of course, refer to her own studies of small groups of children), does not seem to be anywhere beyond the level of technique of any medical man, and although Dr. Boody speaks with no doubt justifiable admiration of the skill of the medical staff, one has that feeling of regret so often felt by readers of the novels of the late Mrs. Humphry Ward. That accomplished novelist was prone to assure us that the conversation of her characters was wonderfully brilliant, but she omitted to give us satisfying examples. What Dr. Boody does enable us to realize very vividly is what an extremely disagreeable place Ellis Island must be. One sees the shepherding of immigrants along passages and into pens:

"People, here again, often criticise the partitions or pens, as they call them, which are used to make the immigrants go in the right direction, or to keep them in the appropriate place. If these critics had once tried to stop a stampede into the wrong place, when 15 different languages would have been needed to make all understand, and when there was no way of knowing which language would cause the desired effect on the leading man, they would need no explanations of the great usefulness of all partitions, not only for the convenience of the examiners, but for accomplishing the greatest saving in the immigrant's time and comfort."

Then there is the period of waiting for the next move—"a time of tension, and specially so for the women, in that the children, who always go with the women, are restless—often hungry and fretful." People will ask questions, too, in unintelligible languages, and "the great skill that all workers at Ellis Island have developed in avoiding, where necessary, direct answers to questions, is very remarkable." What people do when waiting for an examination "is also a matter of great interest. They may walk, or sit stupidly, or sit with a most alert interest in everything that is happening in the waiting room around them. One girl slept. That does not often happen. The process is not conducive to sleep." The separation of members of a family, one perhaps being detained for special medical examination while the others pass on, is attended with some emotional disturbance, but it is comforting to know that "the cause is often traced, not to the main feature of separation and anxiety, but to some small and little unexpected thing." Still, there is evidently some emotional disturbance:

"At the separation point, where one way leads to the Immigration floor, and the other, parallel to it for a distance, leads to the Doctor's rooms, the wire dividing partition is covered with canvas, but after a few yards, the canvas covering is discontinued. Now at the time of separation, there is a shock, and people stop. Moved on by the attendant, as long as the canvas keeps them from seeing their companion, they 'move on,' to stop at once when the removal of the canvas gives a chance to talk, and pass belongings back and forth. This means that the passage is kept from being blocked, and yet that a chance is given for communication, before the pathways finally separate."

For the sheep who pass to the immigration floor the ordeal is almost finished. The illiterate test must be passed at the immigration inspector's desk, certain questions answered, and it is all over. For the goats there is more to come. An immigrant held back for inquiry by a board of three inspectors is not allowed to see his friends, but may call witnesses, and the calling in of the witnesses is, says Dr. Boody, "a most interesting moment to watch." It is so because

"the sister may be looking at the brother for the first time in many years, or a woman, for the first time, may be seeing the man that she has come thousands of miles to marry. Yet in this moment, there is no break in the proceedings. The immigrant is not allowed to speak to the witness—the witness sometimes does not even glance at the bench where the immigrant is sitting. All thoughts center on the inquiry itself. Personal thoughts have no place. But if the verdict is favorable, and the word of admission is briefly announced, witnesses and immigrants, in the midst of tears and embraces, may have to be swept out

of the inquiry room together, by the messenger who has to clear the decks instantly for the incoming case."

Whether some small percentage of the 1,800,000 dollars of annual profit might not be devoted to rendering this interesting moment a little less interesting—after all, prisoners on remand may see their friends—is a question we have not sufficient knowledge to answer. But justification of our opinion that Ellis Island is an extremely disagreeable place has been given, and we conclude by thanking Dr. Boody for her valuable book.

#### THE ABDOMEN IN LABOUR.

THE Oxford University Press has issued, in a book with the title *The Abdomen in Labour*,<sup>2</sup> the essay by Dr. NORMAN PORRITT to which the British Medical Association this year awarded the Sir Charles Hastings Prize. The subtitle is "A General Practitioner's Clinical Study of the Parturient Abdomen," and it is briefly a plea for the importance of the examination of the abdomen in parturition. Dr. Porritt is one of those men who, while engaged in a busy general practice, yet find time, as did the late Sir James Mackenzie, to take careful notes and often drawings of their cases. Dr. Porritt's observations were made during the period of six years preceding 1910, and in that time he accumulated nearly sixty sketches of the abdomen of women whom he delivered, as well as careful notes of the abdominal condition in numerous other cases of labour. The author is very modest in regard to the merit of his drawings, but the important point is that they formed a graphic record which at any rate conveyed much to his own eye, and in many cases must convey a great deal to the eye of every reader.

With the conclusions of the author we need not deal in detail. They reinforce from practical experience arguments that have found their way into most modern textbooks of midwifery. The significance of the book—and in our view this significance is profound—is that here we have a general practitioner coming to the assistance of the specialist authors of textbooks and teachers of midwifery, and proving up to the hilt from his own experience that practice in the abdominal examination of the parturient woman enables one to dispense in very large measure with the procedure of vaginal examination. Dr. Porritt has become profoundly impressed with the numerous advantages which this reduction in the number of vaginal examinations may confer. We offer our cordial congratulations to him, for he has, in our opinion, done a very distinct service to his fellow practitioners by his teaching. We would like to think that this little book, which can easily be read in an hour, and which costs only 5s., will find its way into the library of every general practitioner throughout the country.

#### DIABETES MELLITUS.

THE second edition of GRAHAM'S *Pathology and Treatment of Diabetes Mellitus*<sup>3</sup> contains many alterations consequent upon the advances made in the knowledge of carbohydrate metabolism since the first edition was published in 1923. The treatment of diabetes by insulin has made considerable progress, and Dr. Graham has added new chapters on the special properties of insulin and on the details of treatment with it. These chapters are written with Dr. Graham's customary care and good judgement. He is greatly to be congratulated on the happy way in which he presents his description of scientific facts, and his accounts of the experimental work of himself and others add remarkably to the interest of a book which is essentially clinical.

One point alone occasions some surprise. Dr. Graham inclines still towards a certain degree of undernutrition in the dieting of diabetic patients. He still advocates a "ladder" diet which only brings the patient gradually to a full "maintenance" diet. This has not proved, in the opinion of other observers, so satisfactory as the Toronto

<sup>2</sup> *The Abdomen in Labour*. By Norman Porritt, M.R.C.S., L.R.C.P. (Lond.). London, Humphrey Milford, Oxford University Press, 1925. (Cr. 8vo, pp. xiv + 73; 23 figures. 5s. net.)

<sup>3</sup> *The Pathology and Treatment of Diabetes Mellitus*. By George Graham, M.A., M.D., F.R.C.P. Second edition. Oxford Medical Publications. London, H. Milford, Oxford University Press, 1925. (Cr. 8vo, pp. vii + 162. 8s. 6d. net.)

plan of placing the patient at once on an adequate diet and balancing this diet with sufficient insulin. This plan appears to hold out a better prospect of recovery of carbohydrate tolerance and more likelihood of the patient being enabled to discontinue the use of insulin. For this reason it is doubtful whether Graham's book is to be recommended as one of the best practical guides to the treatment of diabetics. His account of the pathology of the disease is, on the other hand, excellent.

#### DICTIONARIES OF MEDICAL TERMS.

DICTIONARIES of medical terms, or, as they are often erroneously called, for short, medical dictionaries, have been found useful by generation after generation of medical men. Nearly three hundred years ago Bartholomew Castellus published one at Basle, on which, in 1717, Dr. John Quincy of London based his *Lexicon Physico-medicum*, which went through eleven editions. In Germany the excellent *Kritisch-etymologisches medicinisches Lexicon* of L. A. Kraus first appeared exactly a hundred years ago, and Hoblyn's *Dictionary of Terms used in Medicine and the Collateral Sciences* followed very soon after in England and reached its eleventh edition in 1887; it was written, not by a medical man, but by a clergyman, without medical training, although well versed in science. America has been very fertile in medical lexicography. Dorland's and Stedman's books are well known, and Dr. Robley Dunglison's *Dictionary of Medical Science* had attained to its twenty-third edition in 1903.

Dr. GEORGE M. GOULD of Philadelphia brought out in 1890 the first of a series of dictionaries of medical terms, and it is the latest of these that is now before us for review. *Gould's Medical Dictionary*,<sup>4</sup> as this is called, is really the direct descendant of the original *New Medical Dictionary* through its avatars the *Student's Medical Dictionary* and the *Practitioner's Medical Dictionary*. The editor of this and former works, Dr. R. J. E. SCOTT, tells us in his preface that this may be said to be the sum of all of Gould's dictionaries, including no doubt the *Illustrated Dictionary of Medicine, Biology, and Allied Sciences*, as well as the *Pocket Medical Dictionary*. In reference to this last Dr. Scott writes: "If every printing had been called a new edition, the current edition would be the fifty-fifth instead of the eighth."

The *Practitioner's Medical Dictionary* was certainly a compact and handy volume, notwithstanding the fact that it contained 71,000 definitions. The new volume is printed in larger type and on rather thicker and heavier paper, and contains 76,000 definitions and a number of portraits. We must confess that we cannot share the complacency with which the editor writes of these portraits. They seem to us to be very strangely selected and to be artistically unworthy of the reputation of the book. What can be said for a selection which leaves out James Paget and Jonathan Hutchinson but includes John Houston and William Allingham? With the greatest appreciation of the worth of the two latter, we must say that we cannot understand the principles on which the choice was made.

We rise from the study of such a work as this sadder if wiser. It is a saddening experience to find that there are so many hundreds of symptoms, methods, signs, operations, and so on, all called after their discoverers or inventors, but of which we are either forgetful or quite ignorant. It would need the memory of a Macaulay to retain the mere names, let alone the definitions, some of which seek to establish the inventor's claim by fine-drawn distinctions between the new syndrome, sign, or method and its predecessors.

A book, however, in so well known a succession as this needs no recommendation. Its standard of accuracy is generally high, but in a necessarily cursory survey we have noted some lapses from it which might be corrected in subsequent issues. For instance, the definition of Thomas's splints leaves much to be desired. "Lovesickness" is scarcely adequately rendered by "erotomania," which in its proper place is correctly defined as "morbid exaggeration of the affections usual towards the opposite

sex." "Pillion" is probably a mere printer's error for "pilon." Among its 76,000 entries we have failed to find the following: Glisson's sling, Volkmann's ischaemic paralysis, gonad, Scarpa's shoe. Perhaps it would be too much to expect to find such an obsolete term as "algebra chirurgica," which was used in the beginning of the nineteenth century to signify bonesetting—one of the classical meanings of the word "algebra." These defects are noted in no carping spirit, but are recommended to the editor as helps towards that perfection which always recedes before the pursuit of the ardent lexicographer.

#### THE COST OF LIVING.

A HANDY little volume of the "Westminster Library," entitled *The Cost of Living*,<sup>5</sup> by Dr. NORMAN DEARLE, will be of interest and value to many of our readers. The phrase constituting its title is one of the most insistent in the course of popular economic discussions, and the meaning which it connotes is still a most important factor in the remuneration of civil servants and others, and has been frequently referred to in negotiations concerning the proper remuneration of various classes of medical practitioners. To give an exact meaning to the phrase, therefore, and to appreciate the different circumstances and influences which may lead to variations in the cost of living and should be taken into account in calculating those variations, is of great practical importance. These are the things to which a study of Dr. Norman Dearle's book will help us. It requires a little study and not a mere cursory reading, because it is throughout concentrated in matter and closely reasoned. After a careful examination of the real meaning of the phrase—"the cost of living"—consideration is given to the methods of the measurement of cost by means of index numbers. The subject of the relation of prices and costs to real wages or remuneration and the effect of this upon the standard of living of various classes of persons are next discussed. This is followed by an historical review of the course of prices and standards, briefly from the year 1350 to the year 1914 and more fully from 1914 to 1925. In conclusion, certain special problems bearing on the matter are considered: rates and taxes, the co-operative societies, profiteering, and the functions of the middleman.

The book should succeed in clearing away some of the misconceptions as to the method of compiling the Ministry of Labour index number. There is a widespread opinion among many classes that this index number does not in fact correspond to the actual position of affairs; yet, although he recognizes some logical imperfections in its compilation, and even though he suggests that some factors which are commonly ignored (such as community provision of education and health facilities which are in practice taken advantage of by certain classes of the population only) may properly be taken into consideration, Dr. Dearle appears to be satisfied that the index number may still be accepted as sufficiently just in its general application.

It would have been interesting to have had some comment on Professor Bowley's figures of the professional costs of living which were prepared on the basis of actual household budgets supplied by the British Medical Association and given in evidence before the Court of Inquiry on the remuneration of insurance practitioners, but these are nowhere referred to. Those figures, though they are admittedly founded upon an inadequate number of returns, appear to be quite reliable and to afford almost the only actual statistics relating to a middle-class or professional standard of living.

#### A NEW JAPANESE MEDICAL JOURNAL.

AN interesting departure in medical periodical literature has been made by the recently established National Research Council of Japan, which has begun the publication of a periodical divided into thirteen different parts, each dealing with a separate department—physiology, ophthalmology, internal medicine, and so on. The old

<sup>4</sup> *The Cost of Living*. By Norman Dearle, M.A., D.Sc.Lond. The Westminster Library. London: P. Allan and Co., Ltd. 1926. (Cr. 8vo, pp. 163, 3s. 6d. net.)

<sup>5</sup> *Japanese Journal of Medical Sciences*. Transactions: IV, Pharmacology. Tokyo: National Research Council of Japan. 1926. (7½ × 10½, pp. 167; illustrated.)

<sup>4</sup> *Gould's Medical Dictionary*. By George M. Gould, A.M., M.D. Edited by R. J. E. Scott, M.A., B.C.L., M.D. London: H. K. Lewis and Co., Ltd. 1890. (Imp. 8vo, pp. xi + 1393; illustrated. 20s. net.)

established journal *Mitteilungen aus der medizinischen Fakultät der Kaiserlichen Universität zu Tokyo* has in consequence ceased publication after a long and honourable career. The editors of the new journal, which has an English title, *Japanese Journal of Medical Sciences*, will publish papers written in English as well as German, which is undoubtedly a wise course. The system of dividing the journal into separate parts appears to be so far sound that it will make it easier for anyone to find the papers on a subject in which he takes particular interest. Apparently under this scheme a number of a part will be published as soon as a sufficient amount of material has been collected. The success of the scheme will, of course, depend very largely upon the frequency with which it is possible to publish numbers in this large variety of different subjects, for unless these can be issued with fair regularity there will be undue delay in publication.

We have before us the first number of the first volume (Part IV, Pharmacology). It is a substantial production, but the danger of the delay in publication is illustrated by the first paper, which is by Dr. Seiji Ogawa, on tetania parathyreopriva; it is dated December, 1924, but during the past eighteen months a very large amount of important work has appeared on the parathyroids, and the article suffers in some degree from the delay in its publication.

The number contains six articles, and most of them come from the University of Tokyo. An article of particular interest is by Dr. K. Otsuki on the action of yellow phosphorus on bone regeneration; he has performed a large number of experiments, and the article is illustrated with excellent plates; he finds that doses of phosphorus too small to produce intoxication cause an increase in callus formation in fractures and a delay in callus absorption. He concludes, therefore, that the action of phosphorus on the healing of fractures is harmful rather than helpful.

## NOTES ON BOOKS.

DR. J. G. DE LINT, lecturer on the history of medicine at the University of Leyden, has brought out the first instalment of an *Atlas of the History of Medicine*, dealing with anatomy. Dr. De Lint was stimulated to undertake this work by the Vesalian exhibition at Leyden in 1915, and a draft was ready in 1916, but publication was delayed by the war. The 199 figures illustrate the evolution of anatomy from the earliest times down to comparatively modern days, the last two portraits being those of Charles Darwin and the veteran Dutch biologist Hugo de Vries. The first figure is of a clay model of a sheep's liver, which was used for instruction in Babylonian temple schools about B.C. 2000. Some of the figures are from photographs lent by Dr. CHARLES SINGER, who in a thoughtful introduction dwells on the advantages of a study of medical history, and how the method of presenting a series of pictures overcomes some of the difficulties inherent in the study of the history of science. Wherever possible the original drawings of discoverers of anatomical facts have been reproduced, and where this was not available a portrait of the discoverer or of the title-page of his book has been used. The interesting and generally well produced illustrations naturally include a good many Dutch anatomists, some of whom are not so familiar as no doubt they should be—for example, Cornelis van 's Gravezande of Delf and Ysbrand van Diemerbroek Montfoort, both fine full-page portraits. Each illustration is accompanied by a brief description, and attention may be called to the illustrations connected with Harvey and his critics, such as James Primerose of Hull, Jean Riolan, and Caspar Hoffmann, and of his supporters, such as Jan van Beverwyck, Hendrik van Roy, Antony Deusing, and Lazarus Riverius.

The *Hand-Atlas of Clinical Anatomy*,\* by A. C. EYLESHEYMER and T. JONES, contains 395 line drawings, mostly in colour. Some of these are systematic dissections, the various structures being grouped in systems, such as the bones and ligaments, blood vessels, nerves, etc.; others are regional dissections to illustrate the anatomical relations of particular localities. A number of complete sections also show structures as they

appear in frontal, sagittal, and transverse sections. These are all well done, and should help the student. This atlas contains also two other types of picture which will considerably extend the field of usefulness of the book. These are the projection pictures, which represent the deeper structures in their natural position as though the overlying structures were transparent, and the surgical incision pictures, which show the anatomical relations observed in the early stages of the commoner surgical operations. The book is divided into four parts, which deal respectively with the head and neck; the thorax, abdomen, and pelvis; the upper extremity; and the lower extremity. There is an explanatory index intended to render unnecessary any descriptive text to the pictures. The B.N.A. terminology is used throughout in labelling the illustrations. Of course, a large number of the pictures are reproductions of the familiar illustrations of standard textbooks of anatomy, but many of the drawings are original. Considerable ingenuity has been used in sketching out the transparent projections. The book has developed from an earlier and smaller manual of surgical anatomy prepared for the Medical Corps of the American Army and Navy during the war.

The unending stream of additions to methods of diagnostic procedure has compelled Dr. C. L. GREENE, formerly professor in the University of Minnesota, to revise and enlarge his volume on *Medical Diagnosis*, of which the sixth edition<sup>2</sup> has just been received. Basal metabolism is now dealt with in a short special section, and the early diagnosis of cardio-vascular disease receives careful attention, with particular reference to the use of the more modern instruments devised to detect cardiac irregularities. Care has been taken to make the index complete and easy to consult; the illustrations are numerous and good, and the new edition will undoubtedly be as popular and useful as its predecessors.

MR. T. CREW, clerk to the Leicester Insurance Committee, has compiled under the title *Health Compendium and Health Publicity*<sup>3</sup> a book which will be to health workers and members of public health committees what the familiar "Inquire Within Upon Everything" is, or was, to the housewife. There is a statement of the aims and objects, officers, and domicile of every sort of society even remotely related to health, from the Medical Research Council to the Scarpa Society and the Research Defence Society. There are also reproductions of numerous pamphlets, posters, and other forms of literature used in health propaganda in this country, the United States, and in Germany. Some of it is instructive and much of it not a little amusing. We suggest that the author might well exercise some supervision over the contents of the advertisement pages in any future edition.

<sup>1</sup> *Medical Diagnosis for the Student and Practitioner*. By Charles Lyman Greene, M.D., St. Paul. Sixth edition, revised and enlarged. London: W. Heinemann (Medical Books) Limited, 1926. (Sup. roy. 8vo, pp. xxvii + 1468; 709 figures, 14 plates. £3 3s. net.)

<sup>2</sup> *Health Compendium and Health Publicity*. Compiled by T. Crew, F.F.I., F.I.H. Foreword by Professor A. Bostock Hill, M.D., etc. Leicester: The Reader Printing Company, Ltd. (Demy 8vo, pp. v + 260; illustrated. 7s. 6d. net.)

## PREPARATIONS AND APPLIANCES.

### *Administration of Ethyl Chloride.*

MR. JOSEPH M. COPLAND, L.D.S.R.C.S., L.R.C.P. and S.Ed., L.R.F.P.S.Glas., and MR. E. COPLAND, M.R.C.S., L.R.C.P. (Lavender Hill, S.W.), send the following description of a method of administering ethyl chloride which they find minimizes the spasm and toxæmia attending this anaesthesia. A three-way tube, with rubber tubing ends, is led to the tube connecting the mask with the closed bag, and an ampoule of ethyl chloride is inserted firmly in each of the three free ends. After the mask is placed over the mouth, one tube is broken towards the bag with the fingers; the second and third are broken if it is found necessary to prolong the anaesthesia. Before giving the anaesthetic the bag is one-quarter filled with hot water, and this is kept in the bag the whole time. It would seem that the heat and the steam, mingled with the ethyl chloride vapour, have the softening and antispasmodic effect referred to. Hundreds of cases have been done by this method, often the whole mouth being cleared at one sitting.

### *A Micrometer Syringe Apparatus.*

The accurate instrument for the measurement of extremely minute quantities of liquids described by Dr. J. W. Trevan in the *Biochemical Journal*, vol. xix, No. 6, p. 1111, is now obtainable from Burroughs Wellcome and Co. It is known as the "Aga" micrometer syringe apparatus, and is suitable for the measurement of volumes from 0.5 c.cm. (with an error of less than  $\pm 0.1$  per cent.) to those as small as 0.001 c.cm. (with an error of less than  $\pm 1$  per cent.). In immunological work the instrument can measure volumes of the order of 0.01 c.cm. with an error of less than  $\pm 1$  per cent. The price in London of the complete set is £2 15s. Further details may be obtained from Burroughs Wellcome and Co., Snow Hill Buildings, E.C.1.

\* *Atlas of the History of Medicine. I. Anatomy*. By Dr. J. G. De Lint, Lecturer on the History of Medicine at the University of Leyden. With a Foreword by Charles Singer. London: H. K. Lewis and Co., Ltd. 1925. (122 x 81, pp. 28, 189 figures. 5s.)

\* *Hand-Atlas of Clinical Anatomy*. By A. C. Eylesheymer, M.D., and Tom Jones with special dissections by O. E. Nadeau, M.D. London: H. Kimpton. 1925. (Double sup. roy. 16mo, pp. viii + 424; 395 figures. 69s. net.)

## THE POST-GRADUATE HOSTEL, LONDON.

## WHEN NOT TO OPERATE FOR HERNIA.

A DISCUSSION on "When not to operate for hernia" was opened by Mr. W. McAdam Eccles, M.S., F.R.C.S., at a meeting of the Hostel on August 28th. We are indebted to Mr. McAdam Eccles for the following notes of the remarks he made.

Whilst it is a fact that a very large number of cases of hernia should be treated by operation, it is also true that there are a number of conditions in connexion with hernia which negative treatment by operation, or at any rate render such treatment undesirable. I propose briefly to refer to some of these. I will take them specifically under headings.

## I.—THE TYPE OF PATIENT.

## Age.

1. *The very young.* Because: (a) Nature tends to bring about a cure. (b) Very young children do not stand operation well, and a fatality would be a tragedy. (c) Asepsis is, to say the least, uncertain.

2. *The "aged"* (take a man over 60). Because: (a) The tissues are not in most cases such as allow of a radical cure resulting from even a radical operation. (b) Persons do not like operation and then to have to wear a truss. (c) A properly made and properly adjusted truss will bring about such an improvement that the person may not know that he has a hernia, and simply wears the truss as part of his clothing.

## Sex.

*Male.*—(i) In large inguinal herniae it is difficult to occlude the inguinal canal and the apertures—superficial and deep inguinal—sufficiently so long as a passage for the spermatic cord has to remain. (ii) Where there is much disturbance of micturition, the result of enlargement of the prostate.

*Female.*—(i) Cases in which pregnancy is present in the later months; (ii) where the abdominal wall tissues are weak, particularly as the result of stretching from repeated pregnancies.

## Visceral Lesions.

*Heart.*—Advanced cardiac disease negatives an operation for cure. Operation may have to be undertaken for strangulation as a last resort.

*Lungs.*—Any advanced pulmonary lesion. (i) A general anaesthetic is contraindicated, although a local one might be used. (ii) The liability to cough produces a liability for the return of the hernia.

*Kidneys.*—Any advanced disease of the kidneys.

*Liver.*—Especially when ascites is present.

## Some General Conditions.

*Obesity.*—Unless reduction of the fat can be brought about.

*Ptoxis* of the abdominal organs in any marked degree.

*Dermatitis*, until this is cured by proper treatment.

## II.—THE TYPE OF HERNIA.

1. *Inguinal Hernia.*—A largish inguinal hernia with feeble abdominal walls, and with much dilatation of inguinal apertures, is very unlikely to be "cured" by operation. It may be very definitely controlled by proper truss pressure, and this control will tend to cause the danger and discomfort of the hernia to diminish most appreciably. An operation then may place the patient in complete safety, and enable a light efficient truss to be worn with comfort so as to prevent recurrence.

An inguinal hernia which has recurred is very unlikely to be cured by operation, and a suitable truss is then advisable.

2. *Femoral Hernia.*—A femoral hernia of a large size is still more difficult of cure than an inguinal. It is well again to try to obtain control of it by truss, and subsequently to consider operation, with a view, not perhaps of cure, but of rendering the wearing of a proper truss efficient and safe.

A femoral hernia which has recurred is still more unlikely to be cured by operation, and a suitable truss is then advisable.

3. *Umbilical Hernia.*—(a) Infantile acquired: There is a great tendency for these small umbilical herniae in infants to become cured by natural means. Therefore operation is not necessary before, say, 5 years of age. (b) Adult acquired: When there is present a large umbilical hernia in an obese woman, the question of operation is a serious one. It must always be remembered that literally there may not be sufficient room within the abdominal cavity for the contents of the sac. Cure of such herniae by operation is most doubtful, but operation may make the condition such as to allow the wearing of a proper truss with comfort and safety.

4. *An Irreducible Hernia.*—There is no doubt that operation which allows of reduction of the contents of the hernial sac

is ideal, but two points must always be very carefully considered: (i) Can all the contents find room within the abdomen? (ii) Will the operation permit of a truss being discarded?

From the foregoing remarks it will be seen that there are a number of conditions in which operation, to say the least, is not desirable. It is in these cases that a knowledge of the proper types of trusses becomes so very necessary.

## THE ADVANTAGES OF THE HOSTEL.

SIR,—May I draw attention to several points of interest concerning the Hostel? It presents all the advantages of a club with few of its disadvantages.

1. No introduction beyond the presentation of a visiting card is required. This is of importance for Dominion men and women who arrive here unacquainted.

2. There is no entrance fee. This is a consideration for anyone spending perhaps only a week or two in London every few years and to those who can "drop in" only very occasionally.

3. Women practitioners may have access to all the discussions and rooms except the smoking room.

4. A doctor may bring his wife and family, and whilst not enjoying the privileges of the rooms reserved for members they can be at least under the same roof. A ladies' subcommittee will be formed at an early date to care for the interest of the family of a medical man, as it is realized what sacrifices they make when a doctor takes a "busman's holiday."

—I am, etc.,

August 27th.

A. P. BERTWISTLE.

## ROYAL MEDICAL BENEVOLENT FUND.

At the last meeting of the Committee thirty-five cases were considered and £388 10s. voted to twenty-five applicants. The following is a summary of some of the cases relieved.

L.R.C.P., aged 76, is unable to get engagement as locumtenent, although fit to undertake the work; his only income consists of the Epsom pension of £40 and Fund pension of £26 per annum. Special appeal made for help to meet arrears for rent. Committee voted £5. Total relief given by the Fund to March, 1925, £82; elected to an annuity of £26, January 1st, 1926.

Widow, aged 70, of L.S.A. who died in 1897. She has been in domestic service for fifteen years; a year ago she broke her wrist, but pluckily continued working; finally she had to give up and go into the infirmary, where she remained for some months. Recently a lady offered her a room rent free, but the applicant has to pay something towards her maintenance. The Fund voted £12 in twelve monthly instalments of £1 each, and an application has been made for the old age pension.

Daughter, aged 48, of M.R.C.S.Eng. who died in 1910. Her mother died eight months later. She started a small business which she was induced to sell so that she might live with and help some relatives, but was not strong enough to do the work and had to leave them. After various vicissitudes the Charity Organization Society found her starving in an underground room and gave her temporary help. The Fund was able to get her much-needed hospital treatment, but she is subject to asthma and bronchitis and is not sufficiently strong to undertake continuous work. It has been arranged for her to go to a convalescent home, and the Fund has voted her £26 in twelve monthly instalments. Previous relief amounted to £18.

Widow, aged 40, of L.R.C.P.Edin., who, when her husband died in 1923, was left with four children aged 8 to 18 with only £100 a year. A son aged 17 requires help for maintenance whilst studying. Voted £3 for three months. Previous grants for the same purpose total £29 7s.

Daughter, aged 27, of M.R.C.S.Eng. who died in 1907. She is confined to bed with heart disease and her only income is £1 a week, allowed by an aunt. As she requires constant attention a sister gave up a post in Canada to nurse her. The Fund voted £10.

Son, aged 15, of M.D. who died in 1922, was found living in undesirable surroundings. A place was found for him as a telephone boy, but he proved incapable. A suitable home has been found for him and arrangements made for private tuition, as his education was totally neglected by his parents. Fund voted £26 in four quarterly instalments towards his maintenance.

Widow, aged 60, of M.R.C.S.Eng. who died in 1908. She is dependent on daughter, aged 36, who teaches French in Paris. Mother and daughter live in one room. The applicant has been ill. The Fund voted £12 in twelve monthly instalments and a special grant of £5. Previous relief since 1913 amounted to £105.

Widow, aged 71, of M.R.C.S.Eng. who died in 1913. She has a small cottage outside London and supplements her income of £30 a year by letting, from which she has received £41 during the last twelve months. With a friend's help (£20) she has been able to pay her way, but asks for assistance for repairs as the rooms are in a bad condition for letting. Voted £15. Previous relief since 1916 amounts to £28.

Daughter, aged 76, of M.R.C.S. who was in the R.A.M.C. and died in 1891. A condition of residence in a home is an income of £40 a year, and the applicant received only £32 a year from the War Office. The Fund voted £20 in four quarterly instalments. Previous relief since 1921 amounts to £70.

Subscriptions may be sent to the Honorary Treasurer, Sir Charters Symonds, K.B.E., at 11, Chandos Street, Cavendish Square, London, W.1.

The Royal Medical Benevolent Fund Guild still receives many applications for clothing, especially for coats and skirts for ladies and girls holding secretarial posts, and suits for working boys. The Guild appeals for second-hand clothes and household articles. The gifts should be sent to the Secretary of the Guild, 58, Great Marlborough Street, W.1.

## THE BOARD OF CONTROL.

## ANNUAL REPORT FOR 1925.

MANY matters of the first importance, not solely for those whose work is with the mentally afflicted, but for social workers, and indeed for all who are concerned with the public welfare, are discussed in the twelfth annual report of the Board of Control.<sup>1</sup> This report is all the more interesting by reason of the recent publication of the report of the Royal Commission on Lunacy and Mental Disorder, of whose recommendations a sketch was given on July 31st (p. 208). They have borne out in many instances the previous contentions of the Board and of the British Medical Association, and may, it is hoped, expedite long-looked-for reforms.

*Early Treatment.*

The Board has for a long time past pleaded for greater facilities for the treatment, without prior certification, of early cases of mental illness. The Mental Treatment Bill which passed the House of Lords in 1923 would have enabled this to be done; but further progress with the bill was arrested in consequence of the appointment of the Royal Commission. It must be gratifying to the Board to find that this Commission has unanimously endorsed its views, and, recognizing the necessity for early treatment, has recommended the alteration of the lunacy laws to ensure its provision without preliminary certification.

The Commission's desire that treatment of mental disorder should approach as closely as possible to that of physical ailments makes us regret, with the Board, the divorce which has been brought about between the mental hospital and the general hospital and "the failure to recognize that, among the cases grouped under the term insane, there were many whose mental illnesses were short and curable, as to whom the law, rightly solicitous as to the liberty of the subject, need not have insisted upon certification, and for whom, under progressively improving treatment, arrangements in connexion with general hospitals might have been retained with advantage to these patients, and to medicine as a science."

*Need for Increased Accommodation.*

In April of last year two important conferences were held—one to consider the nursing service in mental hospitals, and the other to consider in what ways the need for increasing mental hospital accommodation in England and Wales can best be met. The question of accommodation has given the Board very considerable anxiety. On January 1st, 1926, the number of notified insane persons in England and Wales was 133,883—an increase of 2,332 on the number on January 1st, 1925. This number has no necessary connexion with the incidence of mental disorders in the general population; and, indeed, there is no evidence to show that the incidence of insanity is increasing. It is in consequence of the growth of the population that further accommodation is required. The need for new accommodation is much more acute in some areas than in others. It is intended shortly to call regional conferences, the results of which, it is hoped, will show how best the pressure on the existing accommodation may be relieved.

*Mental Defectives.*

In its report for 1924 the Board gave special prominence to the lack of accommodation for all types of mental defectives. Instead of there being any alleviation of the situation as a result of its appeal the position has become more acute. The response by the local authorities to the Board's invitation to submit schemes for the further provision for mental defectives has been meagre and by no means commensurate with the serious position which was fully explained in last year's report. The Board regards the failure of local authorities to fulfil their duties as hampering the beneficent objects of the Mental Deficiency Act. Out of the 124 local authorities under the Mental

Deficiency Act, only 17 have at present provided any accommodation, and in no case is the provision adequate to the needs of the population of the particular district. "The responsibility," says the Board, "for the degradation, crime, pauperism, and disease which follow the neglect of the mentally defective rests now on the local authorities."

An interesting section of the report deals with the problem of procreation by mental defectives.

"Many of us," says the report, "have had experience of homes where the father or mother is mentally defective, and have been deeply impressed by the tragic lives of the children. Sometimes cruel by nature—more often cruel through ignorance—generally without self control, a feeble-minded parent is utterly unfit to nurse and train children of tender years. It can be shown that many such children inherit mental defect, and though if one parent is normal this is not always the case, it is clearly a misfortune that the child who is not mentally defective should be subjected to the crass stupidity and uncontrolled impulses of a defective parent."

Many tragic case histories bear out the truth of this statement. The Board, whilst suggesting various measures which would diminish marriage and procreation by mental defectives, is none the less inclined to think that the law should be altered so as to provide that marriage by a defective when under Order should be void. Sterilization as a means of preventing procreation is discussed, and does not find favour, for the Board considers that there is a danger of some public authorities welcoming sterilization as a cheap method of ridding themselves of their obligations under the Mental Deficiency Act. The advocates of sterilization, as against the alternative measure of segregation, are answered by the Board in the following:

1. The great majority of mentally defective persons require protection, care, and control on account of their incapacity to maintain an independent existence, and apart from the question of the procreation of children.

2. Unrestricted freedom in a large number of cases would lead to a return to the conditions prevalent before the passing of the Mental Deficiency Act. Sterilization would not prevent these persons from leading useless and harmful lives in and out of Poor Law institutions, prisons, hospitals and refuges, or from spreading venereal disease.

3. As far as immediate expense is concerned, the economic burden to the State is not likely to be lessened by the discharge of sterilized mental defectives.

4. Discharge would not, in our opinion, increase the happiness of the majority of the patients at present under care in institutions.

5. Sterilization as a compulsory measure is likely to arouse public opposition, and so delay the fuller operation of the Mental Deficiency Act.

Sterilization of mental defectives is sometimes advocated, not as an alternative, but as a complementary measure to segregation, but the Board, whilst recognizing its possible application to those cases which are only under permanent institutional care because of the risk of propagation, does not favour it.

*Number of Patients.*

The number of rate-aided patients on January 1st, 1926, was 118,665 (males 49,253, females 68,812), or 88.2 per cent. of all the notified insane. Practically the whole of the increase (2,380) during the preceding year occurred in county and borough mental hospitals. At the close of 1925 there were 695 voluntary boarders, including 142 at the Maudsley Hospital, where the patients are on a voluntary footing, and eight at the City of London Mental Hospital, where, under the Local Act of 1924, patients can now be received on this footing. The total number of certified patients discharged recovered during the year was 6,936. The deaths numbered 8,551. The number of direct admissions was 21,784, and of these first admissions accounted for 17,345, or 79.6 per cent. of all the direct admissions.

The whole report makes interesting and stimulating reading. In a supplement a detailed account is given of the scientific research work carried out in mental hospitals during the year. The Commissioners of the Board are to be congratulated on a report which, testimony anew to their conscientiousness, suggests foresight.

SATURDAY, SEPTEMBER 11TH, 1926.

## MONOTONY.

IN the Section of Medical Sociology at Nottingham, of which the full report appears in this issue, one fact was brought out very clearly—namely, that it behoves the sociologist, no less than every other variety of philosopher, to be most careful in the definition and use of his terms. At the morning session the subject was the physical and mental effects of the monotony factor in modern industrial work; and it was plain that every speaker felt it necessary to apologize for, or to explain, the use of the word "monotony." The opener of the discussion, Mr. Hudson Davies of the National Institute of Industrial Psychology, gave a choice of meanings, quoting Munsterberg's, that monotony is a subjective dislike of uniformity, and Myers's, that monotony is a danger signal of central nervous exhaustion. He himself defined monotony as a reaction, not to selected features of work, but to the whole circumstances of its performance. Miss May Smith, of the Industrial Fatigue Research Board, called attention to the etymological meaning, "one tone," and said that the word represented absence of stimulation. Major Knowles, of Boots' Welfare Centre, asked whether, not being a fisherman, he was entitled to tell a friend sitting on a river bank hour after hour that his occupation was monotonous. Miss Slocock, an inspector of factories, thought that there was no such thing as monotonous work; monotony was a reaction of certain human beings to certain work carried on under certain conditions. Professor Winifred Cullis gave her opinion as a physiologist that the word "monotony" now definitely carried with it more or less of descriptive colour, that a job was monotonous when the general effect was unpleasant, and that monotony connoted an unpleasurable reaction to repetition.

It will be observed that through all these definitions there runs a similarity of idea, and a recognition that a simple word meaning a single musical tone has now received a descriptive colour or a subjective attribute of unpleasantness. It quickly appeared, however, during the discussion, that this descriptive colouring could not be applied to any occupation as such. An occupation that appeared monotonous to one person might be full of interest to another. The besetting sin of the investigator, as Miss May Smith said, is that he puts himself in imagination in the place of the worker, and then judges the work from what he imagines would be its effect on him. It is here that we reach the point at which ill defined terms become a danger. The girl who has hitherto been quite content to stick labels on bottles suddenly learns that she is engaged in a monotonous occupation. Probably she has often heard the word "monotony" used in common parlance without attaching any meaning to it other than boredom. She now learns that monotonous work has physical and mental effects. She begins to feel that her work is monotonous, and through the influence of suggestion spreads the feeling through her group. As Major Knowles said, "to arouse artificial discontent by constantly suggesting that the work is injurious is a futile thing to do." Nothing is easier, said Miss Dowding, than for a discontented worker to turn a

pleasurable job into monotonous drudgery for a whole group of workers.

It would appear that most of those who took part in the discussion attached the factor of monotony to what is called repetitive work. The terms are not synonymous: to make repetitive work monotonous involves not only questions of the frequency and duration of the repetitions, but also the personal equation of the worker. It is possible, however, that until the matter has been more fully investigated it would be better to speak of repetitive work rather than of monotonous work. For it would appear that what the investigators are really concerned with is a disease (or a group of symptoms) called monotony which affects some people who are engaged on repetitive work. Doubtless this adds a further meaning to an ill defined word. Some of the speakers showed a preference to call the disease "boredom."

As regards the etiology of the disease, it seems quite clear that there is a predisposing cause in the temperament of the worker. Mr. Hudson Davies seems to think that the predisposition is universal; he describes the oarsman training for a boat race as becoming bored with training, though he never notices the monotony involved in rowing the race. Mr. Davie also alleged that intelligence is a predisposing cause and also education. Amongst exciting causes is the subdivision of labour, so that the worker sees only small portion of the work, and never the finished article. Miss Slocock called this the absence of "creative" aspect in the work. In some cases, she said, too long and continuous use of a special sense causes monotony, and she told a story of a girl who had to smell every egg that went to the making of biscuits in a factory. It was impossible to do this for more than an hour at a time. Dr. Murrell thought that compulsion produced monotony. Another speaker ascribed it to competition. It was admitted during the discussion that the shortened working day and lessened number of hours a week had largely mitigated the effects of repetitive work.

The symptoms of the disease vary. In one case a worker may become a bad timekeeper, seize every opportunity for leaving work, and become as unsatisfied with her factory as possible without losing her job. Another develops sensations of tiredness, and complaints of pain in the eyes, head, or stomach. A third will gradually lose interest in her work until she develops a "nervous breakdown." Some will develop psycho-neurotic symptoms of a serious nature.

On the proper method of treatment opinion appeared to be largely agreed, as was natural in a body of speakers many of whom were concerned in welfare work. There should be reasonable hours of work with rest pauses when necessary; the environment should be cheerful; singing and conversation should be encouraged where possible; talks about the finished product should be given; supervisors should be chosen carefully in order that there may be no "nagging" interests and recreations outside working hours should be encouraged. There was a difference of opinion, however, on some of the suggestions made. Some speakers thought that change of work was useful. Others were decidedly of opinion that change was often resented. Mr. Hudson Davies thought it necessary that the balance should be held between too much change, which was irritating, and too little, which was monotonous. Anyhow, it seemed quite certain that many girls took an interest in their monotonous work and would resent the jolt to their habits involved in changing to and learning a different process. Several

## THE INSECT VECTOR OF DENGUE.

speakers described the day-dream or reverie as one of the methods by which workers neutralize the monotony of repetitive work, though this method of relief carries with it dangers of the propensity of some welfare word of warning on the part of the speaker. Almost all the speakers ended what they had to say by emphasizing the necessity for vocational selection. Vocational selection may no doubt be regarded as preventive treatment for the disease. Unfortunately it was not considered sufficiently germane to the subject under discussion for the speakers to elaborate their views on the matter. It is perhaps a little curious that people who have had free choice in the selection of their profession—unless perchance they were driven to it by a hard, old-fashioned father—should be found unanimous in advocating outside selection for the children of labour. The free and independent child of the "classes" is allowed to select his vocation, and to kill himself in carrying it out if he chooses. The child of the "masses" is only to exercise his choice within limitations to be dictated by someone else—the speakers did not say whom. It is clear that a youth is entitled to his predilections. But we are equally clear that an employer need not employ a youth whom he considers unfit for the job. But we have a lurking suspicion that the welfare worker and the investigator are after something more. Some are avowedly in favour of a scheme to employ experts to examine aspirants in each trade. Speculation on the intentions of those who advocate vocational selection is interesting, because vocational selection is one of the tenets of the communistic state.

There were two minor points of interest in the discussion. As Dr. Brackenbury pointed out, nearly everyone who took part in it spoke in terms of the female sex. Apparently the thought of the burden of monotony. It was the introduction, plainly, of large quantities of female labour into factories that led to the discovery of the monotony of repetitive processes. The other point of interest was Major Knowles's passing reference—with which we sympathize—to the monotony of the life of the housewife, who has been unable to organize her home and reduce her hours by the introduction of simple repetitive processes.

The whole discussion undoubtedly demonstrated the value of the Section of Medical Sociology, even though we agree with Major Knowles that we should be slow in our judgement of these problems, and, above all, be moderate in our statements.

## THE INSECT VECTOR OF DENGUE.

THE combined issue of the first two numbers of the *Philippine Journal of Science* for 1926 is devoted to a monographic report on Dengue, which is of great interest to all engaged in tropical medicine. The whole is characterized by thoroughness and careful attention to detail, and, although the investigators have not succeeded in isolating the causative agent of this disease, the work commands respect for the great service it renders in confirming certain points which were only probable and clearing up certain others which rested on a doubtful foundation.

They have proved definitely that dengue is a

mosquito-borne disease, that the vector (in Manila at all events, and probably elsewhere) is *Aedes aegypti* (*Stegomyia fasciata* as it used to be called), thus confirming the work of Cleland, Bradley, and McDonald in Australia, and that *Culex quinquefasciatus* (*C. fatigans* of old) is not the transmitter. They have thus shown that Graham was correct in his surmise that the disease was transmitted by a mosquito, but wrong in incriminating *Culex*. They have demonstrated that Graham's "dengue parasite," the *Haemamoeba denguii*, is probably an artefact, as they found the same appearances in normal blood, examination of which had apparently been omitted—another instance of the danger of neglecting controls.

As the result of experiments ingeniously planned and carefully performed the investigators have determined the conditions under which a dengue patient may infect the mosquito. This can happen during a period from a few hours before the first symptoms appear to the end of the second day of the disease, and possibly, though with less certainty, for another twenty-four hours or so, after which mosquito infection fails. They have determined also the conditions under which an infected mosquito may again transmit the disease to man—namely, after the lapse of a period of ten to eleven days, the vector being not a mere mechanical transmitter. No animal other than man has been found susceptible, so there is no evidence of any reservoir host in nature.

For the purposes of experiment and for making accurate clinical observations 64 volunteers were obtained who were perfectly healthy, had resided in the tropics for a brief period only, had never been in a dengue fever district, and had no record of any illness suggestive of this disease. Of this number 52 were infected experimentally by *Aedes* which ten to eleven days previously had bitten a dengue patient in the prodromal period or the first two to three days of illness. No experiments with *Culex* succeeded in producing infection. Clinical observations showed that the time of incubation in 61 per cent. was four to six days, and in 89 per cent. was four to seven days; very exceptionally it was as long as ten days. The symptoms varied much in their severity; some cases were so mild that had not the diagnosis been confirmed by experimental transmission from them it would have been in considerable doubt. It was also found that the onset was less abrupt than is generally believed, as prodromal symptoms were observed for six to forty-eight hours before the initial rise of temperature. In rare instances patients were afebrile throughout the spread of an epidemic.

The authors' deductions as regards immunity are of importance. Of newcomers to Manila from the United States under military conditions about 40 per cent. are attacked during their first year; of these some 30 per cent. may expect a second, and a few a third and even fourth attack. The "acclimatization fever," known locally as *chaptonada*, is dengue. The degree of immunity resulting from an attack is decidedly individual in character, and is rarely solid and lasting. Many went through the succeeding epidemic season without being attacked, but others had relapses or repeated attacks, tending, however, to diminish in severity. The immunity exhibited by native children is probably due to a first attack in early life and constant reinforcement by frequent bites of infected mosquitos.

The points of similarity between dengue and yellow fever are well brought out. For example, that the

patient is infective only up to the third day of illness; that there is a period of development of the virus in the mosquito of the same duration before it is able to infect another human subject; that the virus, which is still to seek, is, at one stage at least, filterable, present in the peripheral blood of the patient, and transmissible to non-immunes by the blood or filtrate; that epidemics only arise when there are simultaneously present cases of the disease, large numbers of *Aedes aegypti*, and large numbers of non-immune individuals. On the other hand, the mortality from dengue is nil, and the degree of immunity weak and variable, both of which points are the direct converse of what obtains in yellow fever. Prevention is summed up in antimosquito measures and the co-operative efforts of individuals, healthy and sick.

There are other points in the report of much interest—such as the history of the condition, details of the arrangements for breeding and storing mosquitos, special points in the bionomics of the insect, the epidemiology of the disease in the Philippines, which space alone forbids our dealing with here. The report is clearly written and well produced, and misprints are very few, the most noticeable being that Sir Rubert Boyce is named Rupert throughout, a point which does not detract from the scientific value of this excellent record.

#### JONATHAN HUTCHINSON'S MUSEUM.

THE new buildings of the educational museum were opened at Haslemere on August 27th by the Earl of Middleton. The museum was founded thirty years ago by Sir Jonathan Hutchinson, who not only made many gifts to it, but also applied certain ideas of his own in the matter of arrangement which were then considered revolutionary, and even yet have not found general appreciation. Since his death, up to which time he defrayed the whole cost of maintenance, including the services of a curator, the work has been continued by voluntary contributions, and last year it was decided to acquire more permanent and central quarters as a memorial to the founder. A house and grounds were purchased, and were adapted to museum purposes by one of Sir Jonathan Hutchinson's grandsons, and in this new setting—much more suitable than the series of huts in which the specimens had previously been lodged—the collections are seen to advantage. The museum contains sections on geology, botany, natural history, and the history of mankind, as well as a local exhibit to which it is the pride of the people round about to contribute. Lately the museum has been enriched by the gift of a section illustrating peasant art, the nucleus of which was formed twenty years ago by the Rev. Gerald Davies, now Master of Charterhouse, who gathered articles, such as mangle-boards and other domestic implements, as well as textiles, mostly in the remoter parts of Scandinavian countries. An excellent ornithological collection has been rearranged to illustrate, not only what some birds are like, but their migrations and life-histories and economic value. The governing principle of the museum is still Hutchinsonian simplicity and unpretentiousness, and the interpretation of science in a direct, pictorial, and diagrammatic way. One of Sir Jonathan Hutchinson's ideas, carried out on a large scale, is his "space for time" method, whereby the walls are arranged in vertical panelings, each panel representing, in the historical section, a century, and in the geological section a period; exhibits—pictures, printed information, or specimens—are arranged in the appropriate spaces. The ceremony at the opening of the new buildings was presided over by Dr. Arnold Lyndon, O.B.E., chairman of the committee of manage-

ment, who recited briefly the particulars just given, and drew attention to some of the outstanding exhibits. Lord Middleton said that Jonathan Hutchinson was a great surgeon, naturalist, and investigator, but those who knew him best would perhaps think of him first as an educationalist in the sense that he wanted to bring to every community in its own locality the results of scientific research, and to do so in the most simple and direct way. A visitor to an ordinary museum might often plaintively ask what, humanly speaking, a particular specimen was, but under Sir Jonathan Hutchinson's guidance a museum became not only human but exciting. An address on Hutchinsonian method was given by Dr. F. A. Bather, F.R.S., keeper of the geological department of the South Kensington Natural History Museum, who said that Sir Jonathan Hutchinson was accustomed to set his educational museum rather in contrast to the ordinary local museum, though possibly a synthesis of the two might prove the most advantageous. Hutchinson's idea was that the museum should be for the untaught. He also dissented from the view that the museum should be a mere addition to book knowledge; it was to be a compromise between the printed book and that outside nature study opportunity for which it was so difficult for an urbanized community to obtain. Hutchinson taught through concrete objects; to his mind no museum worthy of the name was simply a "series of labels illustrated by specimens"; it was to be a series of specimens which as far as possible told their own story. Another point on which this master in museum making insisted was that objects as far as possible should not have to be viewed through glass. If the injunction "not to touch" could be waived so much the better. Things were best seen when the fingers assisted the eyes. Hutchinson also followed the plan of first asking his questions of his students and then turning them loose among the material to gather their answers—a better plan, Dr. Bather thought, and one worthy of extension into larger fields, than the usual method of taking students through a course of study and putting the questions at the end. A vote of thanks was proposed by Mr. H. A. L. Fisher, lately Minister of Education, who, however, declined to be drawn into a tempting discussion, and was seconded by Dr. Roger Hutchinson (Haslemere), who remarked that when his father started his museum his ten irreverent children thought it was a device for forcing more knowledge down their unwilling throats. His father was devoted to the demonstration method; if he shot a rabbit in the field he would immediately open the animal and demonstrate its anatomy to his sons, or he would pluck a flower to pieces while he talked about stamen and pistil. A primrose by the river's brim meant to Hutchinson far-reaching Darwinian theories and much else. On behalf of the family he expressed gratitude for this living memorial in which another soul went "marching on." At the close of the proceedings a memorial tablet commemorating Hutchinson's great work among his Surrey neighbours was unveiled.

#### THE DEFINITION OF MENTAL DEFICIENCY.

A new Mental Deficiency Bill has been passed by the House of Lords, and was ordered by the House of Commons to be printed on July 29th last. It will be considered by the latter House in the autumn session. The main purpose of the bill is to alter the definitions of defectives as set out in the Mental Deficiency Act, 1913. It is a curious fact that neither in that Act nor in any other is there any definition of mental defectiveness; there are only definitions of the several classes of defective persons—idiots, imbeciles, feeble-minded persons and moral defectives, or "moral imbeciles," as they have hitherto been termed. The

definitions in the case of the first three classes require that the mental defectiveness must have existed "from birth or from an early age," and in the last class that the particular conduct they manifest must have been displayed "from an early age." For some years these definitions have been found to have important administrative disadvantages in at any rate two respects. In the first place, magistrates, in order that they may deal properly and legally with persons before them, have required evidence that the undoubted present mental defectiveness of those persons had existed "from birth or from an early age," and such evidence it has naturally in some cases been difficult or impossible to produce, although the nature of the case might not be seriously disputed, or might, indeed, be convincingly evident to any medical or psychological expert. In the second place, an increasing prevalence of encephalitis lethargica has led to a considerable number of cases in which a very real arrested development of mind has arisen in the course of childhood or adolescence, therefore, of course, not inherent or germinal or congenital, but definitely acquired. It is very desirable that there should be power for authorities to deal appropriately with cases of this nature. The new bill proposes to remedy these defects, or to effect these purposes, by eliminating the words "from birth or from an early age" from the old definitions of the classes of defectives, and to add that for the purposes of the Act mental defectiveness shall mean "a condition of arrested or incomplete development of mind whether innate or induced after birth by disease, injury or other cause." The new definitions, in what is now probably their final form, may be regarded as satisfactory, but they have not reached that final form without a good deal of thought and trouble on the part of the Board of Control, the Medical Committee and Council of the Central Association for Mental Welfare, and others interested. From the medical aspect the danger has been lest the new definitions should lead to the ignoring in practice of the fundamental distinction between the arrest of mind taking place before the developmental period is ended, and a perversion or decay of mind occurring after the mind has attained normal development, and so include, in fact, cases of insanity which were never intended to be, and should not be, dealt with under the Mental Deficiency Acts. This distinction does not need emphasizing to medical practitioners, but to some others who have to take an important part in administering or enforcing the law it seems necessary to insist upon it. It is unfortunate, therefore, that the words "arrested or incomplete development of mind," occurring towards the end of Clause 1 of the bill, are not stressed in the explanatory memorandum prefixed thereto, as they should have been, but are rather slurred over and have their meaning obscured or weakened in the first paragraph of that memorandum. It is true that the preface is no part of the bill, but it is what many people read instead of the bill itself, and it is of some importance that the meaning should be made clear and the emphasis properly placed when the bill next comes before the House of Commons, so that there shall be no misunderstanding as to its application and administration.

#### THE NEW INTERNATIONAL SANITARY CONVENTION.

IN July last Sir George Buchanan read an address before the conference of port sanitary authorities, at the Jubilee and London Congress of the Royal Sanitary Institute, on the recent revision, at the conference held at the Office International d'Hygiène Publique in Paris, of the International Sanitary Convention for dealing with the chief "pestilential" diseases which are liable to be carried by shipping. The chief diseases were cholera, plague, typhus, small-pox, and yellow fever; and Sir George Buchanan pointed out that British influence in framing regulations

had been exerted uniformly on the side of freedom. All systems which involved long detention in quarantine had been contested; in regard to cholera the application of the authorized conventions had been proved to be consistent with a minimum of interference with passengers and crews, and practically no interference at all with merchandise. The carriage of plague infection by ships required different measures from those adopted against the carriage of cholera. Human plague cases, whether on ships or on the shore, were quite an uncertain factor; ports became infected one after the other through the carriage of plague rats. It was necessary, therefore, to suppress rat plague on ships, to prevent the access of rats from ship to shore, and to keep down the rat population in wharves, docks, and warehouses. The methods adopted were systematic rat-catching, fumigation with sulphur or with cyanide gases, rat guards to prevent landing, and various schemes for dealing with the discharge of cargo likely to harbour rats. The International Sanitary Convention of 1912 provided some measures of co-ordination, but there were obvious deficiencies, one of the worst being that a ship which swarmed with plague rats would be classified as "healthy" and not as "infected" if no human cases had occurred during the voyage. Sir George Buchanan said that yellow fever had been diminished almost to the point of extinction by quarantine in its newer sense of restrictive measures scientifically applied. Typhus and small-pox had required measures subject to some general rule, so as to avoid friction and dispute between different nations. In preparing the new convention one of the first points concerned the arrangements between different countries to inform each other of the prevalence of the disease. The Office International endeavoured to get rid, as far as possible, of provisions based on formal declarations that a particular port had been infected, and to increase the means by which countries might obtain information of the prevalence of the diseases from any part of the world—for example, through the consular services and the Health Organization of the League of Nations. The new convention required the signatory Governments to reply to any inquiry addressed to them by the Office International d'Hygiène Publique in Paris for information about the transmission of infectious disease from one country to another. The convention also improved and simplified the declaration which Governments are required to make by means of their consular services, and imposed a new requirement that these occurrences should be notified direct to the Office International, which would decide on the methods of distributing knowledge of the facts. With regard to rats, the conference adopted a system by which each country should undertake to do its best to ascertain the conditions of rats in its ports, and to communicate the results to the central office in Paris. The convention, therefore, aimed at : lying responsible authorities in each country with the fullest possible information, leaving the countries to decide what action, if any, was necessary. It also laid down a code of measures which were applicable to the ship, passengers, and crew, and this code had been made strictly reasonable, and the measures suggested constituted a maximum. No obligation had been imposed on any Government to take the measures prescribed in the code. An important article in the convention recommended the conclusion of special agreements between individual countries to make the sanitary measures "more efficacious and less burdensome," and to encourage preventive action, such as vaccination, at the port of departure. After considerable criticism of the use of bills of health, the conference recommended that such bills should be issued free, that fees for consular visas should be reduced, that the bills should be set out in one of the languages recognized in maritime commerce, and that the gradual abolition of bills of health should be aimed at. A separate code had

been made for "infected," "suspected," and "healthy" ships according to each disease in question. Provision had been made for protective cholera inoculation. The full inspection of ships for rat plague was authorized; where the ship was "healthy" and there was no evidence of rat plague or unusual mortality amongst rats, fumigation was not entirely forbidden, but was only to be undertaken in exceptional cases and for good reasons. Particular ports were to be designated as sufficiently equipped to undertake effective destruction of rats, the process would be undertaken not more often than once in six months, and a certificate that it had been done, specifying the methods and results, would carry the ship on to the next half-yearly examination. The inspection officer was authorized to exempt from "deratization" when circumstances permitted, and the exemption certificate had the same six months' validity as the "deratizing" certificate. In conclusion, Sir George Buchanan said that while the new convention was not a world-shaking instrument of hygiene, it embodied a practical world code which should assist administration, and at the same time furnish a reasonable protection to the freedom of commerce and transit.

#### SIR HENRY ACLAND.

In the *Times* of September 4th appeared an announcement of the gift to the Bodleian Library of the correspondence of that great personality the late Sir Henry Wentworth Acland, Bt., K.C.B., M.D., F.R.S. (1815-1900), of Oxford, who, finding medical science in the "home for lost causes" in a state of suspended animation in the early and mid-Victorian periods, brought it to life by his vigour and far-seeing wisdom. Coming of an old Devonshire family, the fourth son of the tenth baronet (creation 1678, with precedence from 1644) of Columb-John, he was created a baronet in 1890, was President of the General Medical Council for thirteen years (1874-87), and Regius Professor of Medicine at Oxford for thirty-six years (1858-94). He was a most striking figure, and, like his friend Henry Liddell, the great dean of Christ Church, combined handsome impressive features with the highest intellectual culture in a way seldom rivalled. An artist and lifelong friend of John Ruskin, it was indeed fortunate for Oxford that he directed the building of the University Museum; this interesting story has been told more than once—by Ruskin and himself in 1859, by Dr. H. M. Vernon and his wife on the jubilee of the museum (1909), and by Sir Henry's son Dr. Theodore Acland in the "Contributions to Medical and Biological Research, dedicated to Sir William Osler in Honour of his Seventieth Birthday" (1919), in which there are most appropriately portraits of Sir Henry Acland and John Ruskin. His wide sympathies, versatility, and personal influence did a unique service in promoting the study of natural science in Oxford. Looking back on Sir Henry's plans in the eighties for medical education and the developments of public health and State medicine, we discern now a marvellous foresight and accuracy which then may have appeared visionary. His correspondence of six thousand letters should be a mine of information about the history of the science and medical school of the University of Oxford, and show even more clearly what a great man he was.

#### A CONFERENCE ON CANCER.

A CONFERENCE ON cancer is to be held at Lake Mohonk, New York State, on September 20th, by the invitation of the American Society for the Control of Cancer. The conference will last for the greater part of a week. Its main purpose is to ascertain what measure of agreement on the various problems of cancer in which the public are

interested can be reached by discussions between pathologists and clinicians of America and European countries. The representatives from this country are Sir John Bland-Sutton, Past President of the Royal College of Surgeons of England, Dr. J. A. Murray, director of the Imperial Cancer Research Fund, Dr. Archibald Leitch, director of the Cancer Hospital Research Institute, and Mr. Sampson Handley, surgeon to the Middlesex Hospital. In addition to these there will be about a dozen delegates from various European countries, including Professor W. M. de Vries (Amsterdam), Professor H. T. Deelman (Gröningen), Professor Gustave Roussy, Dr. C. Regaud, Professor Hartmann (Paris), Professor Bérard (Lyons), Professor Marié (Toulouse), Dr. C. du Bois (Switzerland), Professor Maisin (Louvain), and Dr. R. Bierich (Hamburg).

#### PRE-MEDICAL INSTRUCTION IN AMERICA.

We welcome the first number (July, 1926) of a new series of the quarterly *Bulletin of the Association of American Medical Colleges*, stated to be "the only publication in the world devoted to medical education and medical pedagogy." It has been resuscitated after an interval of thirteen years, for the first series was brought to a close by financial stress after two years' existence. Besides much news, it contains the views of educational authorities, such as deans of the medical schools; in this instalment there are expressions of opinion on the two years of pre-medical study which, though of course presented from the American standpoint, may not be devoid of interest in this country, and even, perhaps, capable of some degree of application. Some of the teachers feel that too much attention is given in these two years to scientific subjects to the neglect of the humanities, and that there is therefore a risk of excluding from the medical schools those students with the broader human interests and knowledge of the forces governing behaviour. Samuel P. Capen, Chancellor of the University of Buffalo, asks the familiar questions: (1) Which is the more important for the medical student, a thorough grounding in the basic sciences or a wider general education? and (2) Is it possible to improve the accomplishments in the natural sciences and at the same time to provide a broader and better education in other directions? He is in favour of curtailing the scientific preparation and making it more attractive to the student, who often fails to see its object, except as a disagreeable preliminary penalty which must be paid for the privilege of studying medicine; to achieve this he would introduce into it illustrations from material now reserved for the medical school. A considerable amount of the social sciences, especially sociology, psychology, economics, and history, should, he thinks, be added to the curriculum of the two years spent in pre-medical study. Professor Hugh Cabot, Dean of the Medical School of the University of Michigan, while inclined to think that more scientific work, such as physical chemistry and biophysics, should be taught, and that the instruction in English and rhetoric should, if anything, be increased, expresses a doubt whether, apart from culture, the learning of French and German adds anything essential to the equipment of the medical man, since the greater extent to which foreign literature is available through translations has altered the situation to an important degree in recent years. It appears that at Michigan University, at any rate, this bold and rather striking conclusion has been arrived at; no doubt the abandonment of the widely held ideal of a knowledge of these two modern languages has been reached only after due consideration and the realization that in practice the student is seldom able to read freely the language he takes up for admission, and as he rarely uses the knowledge the time thus expended has really been lost.

## INFANT WELFARE.

MUCH work has been done and much has been written in recent years on the determining causes of infant mortality. Special interest nevertheless attaches to a contribution to the subject by Miss E. M. Elderton of the Galton Laboratory in a memoir on the relative value of the factors which influence infant welfare.<sup>1</sup> The first section of the memoir and part of the second were published last year, and were reviewed on January 9th (p. 59); the remainder of the second section has now appeared, and further sections are to be issued later. Miss Elderton is a recognized authority on the application of modern statistical analytical methods to problems bearing on the relative importance of the influence of heredity and the various environmental and social factors in determining types of disease, and has made so detailed an analysis of the various factors that her conclusions must be of considerable general interest and of much value to those who have to deal practically with infant welfare. The data on which the investigation is based were derived mainly from the five North Country towns, Blackburn, Preston, Salford, Rochdale, and Bradford, and were provided by the respective medical officers of health. In Blackburn, Preston, and Salford the information relates to babies who were born in 1908; in Rochdale to those born in 1909 and 1910; and in Bradford to those born in 1911 and 1912. The number of infants comprised 500 from Blackburn, 633 from Preston, 854 from Salford, 4,006 from Rochdale, and 2,931 from Bradford. All the particulars were obtained by lady inspectors or health visitors. Some data relating to the city of Birmingham in 1908 derived from a report by Sir John Robertson, and data for the district of Westminster, London, from reports of the City of Westminster Health Society, were also considered. The baby who had been under observation for a year was the centre of investigation. As the problem for solution was the arrangement in order of importance of the factors that influence the infant death rate and the health of the surviving children, the method of correlation was employed for the analysis, and the correlation coefficient was used in its various forms—the product moment, the biserial, and the fourfold. Partial correlations also were used to distinguish the influence of certain interrelated factors. The death rates per 1,000 births for the various comparable groups were also tabulated. The first section of the memoir deals with the influence of various environmental and parental factors on the viability of the child. The term "viability" is used in preference to "mortality," as the latter word has more the idea of a rate behind it. The principal conclusions are that the health of the mother is an important factor in determining infant mortality in the data examined, and that the habits of the parents and the occupation of the father both show a small association with infant mortality. Both the health and habits of the parents are associated with the various environmental conditions considered, and allowance must be made for parental health before any statement can be made as to the relative importance of the environmental conditions for infant viability. When this correction has been made very little association is found between infant mortality and any environmental condition. Any association that exists between the employment of the mother and infant mortality is very slight; in the majority of districts there is none. When any association is present it is chiefly a secondary result of the presence of inferior stock, and the correlation is made insignificant by retaining the habits of the parents constant. There is no evidence that the employment of the mother, in itself, leads to lack of

cleanliness in the home. There is a rather higher infant death rate among first-born than among later-born children, but later-born children in larger families do not show less vitality. If any such tendency exists it may be ascribed to the fact that the parents have bad habits. Evidence of the influence of the age of the mother is conflicting; there is a heavier death rate in infants of mothers under 23 years except in Bradford, but more data are required. No evidence is found that bottle-feeding in itself causes a high infant mortality. In the majority of cases bottle-feeding follows poor health in the child, and does not cause it. It is held, however, that this subject calls for fuller consideration. Poverty, whether judged by the wage of the man or the income of the family, was not found to be associated with infant mortality except to a slight extent, and this association disappears when the health of the mother is made constant. It appeared that the type of housing has very little influence on infant mortality, and that indoor sanitation had no advantage over outdoor sanitation so far as infant mortality was concerned. Miss Elderton urges the need for more complete statistics of the factors that have an influence on infant welfare, particularly as to the health of the parents, and to the attack rate of certain diseases in infancy; she asks also for some method which would make it possible to identify on entrance to school, for the purpose of further inquiry in regard to health and social conditions, the children whose circumstances have been the subject of investigation in infancy.

## PLAYING GROUNDS FOR THE PEOPLE.

IN these days when vast areas in the vicinity of all large towns are being converted into residential neighbourhoods for various classes of the population, it is well that there should exist such an organization as the National Playing Fields Association. The movement was inaugurated at a meeting in the Royal Albert Hall on July 8th, 1925, under the presidency of the Duke of York. In town planning the provision of open spaces for recreation has often been overlooked; and it has been urged that the Ministry of Health should give closer attention to the matter, and co-operate with local authorities in establishing playing fields in places where extensive building is going on. In the meantime the National Playing Fields Association is endeavouring to support local authorities and other bodies in any steps they take to provide the people with adequate recreation grounds. It advocates an extension, with such variations as may be necessary, of the scheme started in Oxford in 1920 by Mr. J. R. F. Turner, whereby boys of the elementary schools are permitted to use college cricket grounds when these are not required by the undergraduates. Certain public schools have offered similar facilities and practice classes have been instituted at Lord's. The object of the association seems worthy of every support, not only in neighbourhoods that are being suburbanized or developed into towns, but also in many villages throughout the country where playing grounds seem sadly lacking. The address of the National Playing Fields Association, which is now being organized on a county basis, is 166, Piccadilly, W.1.

## THE MEDICAL REGISTER: UNTRACEABLE PRACTITIONERS.

At the request of the Registrar of the General Medical Council we publish in the SUPPLEMENT this week a list of the names of medical practitioners who have not replied to his inquiries as to the accuracy of their postal addresses. Any practitioner who finds his or her name included in this list and desires it to be retained on the *Medical Register* should communicate at once with the Registrar, General Medical Council, 44, Hallam Street, Portland Place, London, W.1.

<sup>1</sup> On the Relative Value of the Factors which Influence Infant Welfare. By Ethel M. Elderton. *Journal of Eugenics*, vol. 1, Parts III and IV, April, 1925, pp. 277-321. Cambridge: The University Press. (Med. 4to; illustrated. Annual subscription, 50s. net; double parts, 35s. net.)

## THE STATE OF THE PUBLIC HEALTH.

## SIR GEORGE NEWMAN'S REPORT FOR 1925.

ENGLAND AND WALES.

[First Notice.]

THE annual report of the Chief Medical Officer of the Ministry of Health, which has now been issued,<sup>1</sup> deals with the state of the public health in England and Wales during 1925; the statistics in it are drawn from the Registrar-General's returns relating to births, deaths, and infectious diseases, and the various data and records in respect of invalidity under the National Health Insurance Acts. Supplementary information has been obtained from the annual and special reports of medical officers of health, from investigations by medical officers of the Ministry, and from the work of other governmental departments concerned with the physical, industrial, and social welfare of the people.

The report contains twelve chapters and four appendices, and is characterized by a quiet optimism as regards the progressive triumph over preventable disease. In this respect a warm tribute is paid to the valuable work of the insurance medical service, to which one chapter is devoted, and also to the increasing amount of attention to maternity and child welfare.

*Births and Deaths.*

The birth rate during 1925 was lower by 0.5 per 1,000 than that of the previous year, and by 7.2 as compared with 1920, which was the apex year of the increase in birth rate which followed demobilization. The death rate was just under 12.2 per 1,000, approximately the same as last year. Sir George Newman repeats the statement in his previous report that the crude mortality rate is likely to show a slight upward tendency in the coming years in consequence of a change in the distribution of age groups of the population, and not attributable to any strengthening of the conditions prejudicing vitality.

The following diseases were prominent in the mortality rates, the figure in each case being the proportion in 1,000 deaths: cardiac and circulatory diseases, 177; bronchitis, pneumonia, and other respiratory diseases, 165; malignant diseases, 110; diseases of the nervous system, 99; and all forms of tuberculosis, 85. Comparison of these figures with those for last year shows that whereas in 1924 the principal cause of death was respiratory disease (174), the leading place in 1925 was taken by diseases of the heart and circulation, which have increased from 163 to 177. In the two years 1924 and 1925 the figures for malignant disease are respectively 106 and 110; for tuberculosis 87 and 85, and for diseases of the nervous system 100 and 99. By classifying the total deaths in age periods it appears that there is practically no change in the two years in any group except for a slight decline in the first four years of life.

*Infant Mortality.*

In a table of the infant death rates for various age periods since 1881, it is shown that the reduction in mortality has affected mainly the age period of 3 to 12 months: the death rate under 4 weeks still remains relatively high. As regards the causes of death, an increase in whooping-cough was counterbalanced to some extent by a decrease in influenza. The maintained low level of infantile mortality (75 per 1,000 births) indicates that there was in 1925 a saving of some 37,000 infant lives. It also implies a healthier physical condition in children from 1 to 5 years of age, and a better state of personal and public hygiene. Sir George Newman adds that there is still room for further reduction, particularly as regards the exceptionally high mortality in the first four weeks of life, and the mortality among the illegitimately born, for whom the death rate under 1 year per 1,000 born was 136, as compared with 75 for all births.

*Mortality due to Respiratory Diseases.*

Although respiratory diseases came second in the list of causes of death during 1925, Sir George Newman devotes special attention to them in view of the possibility of their reduction by preventive measures. Influenza has retained its unhappy prominence. Each year since 1918 (except 1923, and for females 1921) has been characterized by a higher influenza mortality rate than 1906 to 1910, and both 1922 and 1924 surpassed 1891-95, the previous worst quinquennium. Pulmonary tuberculosis, on the contrary, has continued to decline; no year since 1918 had so high a death rate as 1906-10, and the rate for 1924 was for males only 74 per cent., and for females 79 per cent., of the rate for the five-year period. Other respiratory diseases in this respect occupy a middle position between influenza and pulmonary tuberculosis; the death rate for 1924 showing an improvement on the 1906 to 1910 figures of 16 per cent. for males and 17 per cent. for females, which is a greater relative improvement than has previously occurred. Commenting on the variation in death rates due to respiratory diseases since 1851, Sir George Newman recalls the observations of William Farr, who, after studying the increasing death rates due to bronchitis and pneumonia from 1850 onwards, suggested in 1866 that smoke pollution of the atmosphere as a probable cause should be dealt with. He returned to the attack with more decision in 1869, and urged the adoption by manufactories and kitchens of smoke consumption. In 1871 Farr admitted that the still increasing death rate might be partly due to change of nomenclature and improved pathology, but he also incriminated imperfect ventilation and dusty conditions in mines, shops, and factories. In 1875 he referred to risks in this respect arising from atmospheric temperature changes, one of his favourite lines of study, and again insisted on the importance of particles in the air. Sir George Newman remarks that Farr was well acquainted with the factors to which most importance is still attached. Under the heading of "Variation of mortality in districts," reference is made to the Registrar-General's annual report for 1913, which contained a table of pneumonia mortality rates in county boroughs, urban districts, and rural districts throughout England and Wales. Sir George Newman states that the death rate from pneumonia in 1924 in each of these classes was substantially the same as in 1913, and he quotes the words in the 1913 report: "Evidently pneumonia is to a large extent a preventable disease, and the North of England has still much to learn with regard to its prevention." He adds, as his own comment, "In a word, pneumonia is mainly a disease of industrial and urban districts, due to the total complex of town life." He then passes to the regional distribution of pneumonia notifications, and cites the year 1923, which was not conspicuous for any heavy influenza mortality. A table of incidence rates during four-weekly periods of this year demonstrates the unfavourable prominence of the northern and north-western parts of England compared with the rest of the country, the high incidence in the counties of Lancashire and Cheshire being particularly significant. The occurrence of harsh climatic conditions does not appear to explain these results fully, though statistical evidence indicates that sharp changes of temperature, particularly in their effect on the aged, are the real basis of the evil reputation of climate in relation to respiratory disease. Thus the maximum of mortality is reached, not in mid-winter, but in the early spring, in March, a time of great temperature variations. Generally speaking, a fall of temperature below the average for the season is coincident with an increased mortality; other instances of this relation were included in a special report by the Ministry on the influenza pandemic which was discussed in the JOURNAL, 1921 (vol. i, pp. 205, 348, and 355). The increase of mortality is not to be considered an inexorable consequence of a fall of temperature, for other factors have a modifying influence, and their statistical evaluation is a very difficult matter. Sir George Newman urges the necessity of more experimental and small-scale investigations, and concludes that there is undoubtedly an excessive rate of mortality in the north-western part of England from respiratory diseases which could be ameliorated by an increase of knowledge

<sup>1</sup> On the State of the Public Health. Annual Report of the Chief Medical Officer of the Ministry of Health for the year 1925. H.M. Stationery Office. (Med. 8vo, pp. 240. 3s. net.)

how to live healthily and a right use of measures of prophylaxis and treatment. He adds:

"Every form of industrial or mechanical contrivance which either prevents or reduces pollution of the atmosphere is a contribution to the public health, and this aspect of the problem calls for the continued and vigilant attention both of authorities and those responsible for commercial concerns. But this is not all. There is needed an increase in the knowledge and practice of healthy living. Much can be done by personal prudence; by cleanliness, by exercise, by correct breathing, by domestic ventilation, and by the practice of individual hygiene."

With reference to the part played by respiratory infection, Sir George Newman recommends regular bacteriological examinations of samples of the population in different places, and thinks that in this way it will be possible to forecast epidemics of respiratory disease, as has been accomplished in the case of cerebro-spinal fever. He does not believe that any form of treatment by drugs or vaccines is at present generally applicable, though in all acute respiratory infections early medical treatment and competent nursing are of supreme importance. Such treatment consists of rest, the maintenance of the patient's strength, the appropriate oxygenation of his blood, and the sustenance of his circulation. He considers that at present the effective provision of hospital accommodation for respiratory infections is proportionately inadequate, and suggests that treatment in isolation hospitals might well be extended to include that of respiratory diseases. He closes this section of his report with the following words:

"Lastly there is need for much more intensive study of pneumonia. Medically, we want more knowledge of its bacteriology, modes of transmission, relation to primary and antecedent disease—fatigue, colds, influenza, measles, whooping-cough, trauma, alcoholism, heart disease, diabetes, and renal disease. Socially, too, there is need for exact investigation of the depressant influences and circumstances which predispose to pneumonia."

#### Small-pox.

Small-pox continues to increase; 5,365 cases were notified in 1925, as compared with 3,765 in 1924, 2,485 in 1923, 973 in 1922, and 315 in 1921. In addition to these 5,365 cases local inquiries resulted in the discovery of fifteen other cases, but twenty-six of the notified cases were not confirmed as being small-pox by the Ministry's officers or the medical superintendents of small-pox hospitals, so that the net total number of cases which came under observation during 1925 was 5,354. Six patients died. Sir George Newman refers regretfully to the misunderstanding and misrepresentation which have resulted in the confusing in the lay mind of the medical question of the merits of vaccination with the administrative question of its compulsory application. An unfortunate sequel has been that the concession granted in 1907 by Parliament to the natural repugnance to compulsion has been misinterpreted as a weakening of professional belief in the efficacy of vaccination, which, nevertheless, in the opinion of those best qualified to judge, remains the one and only certain protection against the spread of small-pox. The general distribution of the disease in counties resembled that in 1924, but there were 1,138 cases in Durham as compared with twenty in the previous year. Control of the disease in that county was rendered difficult by inadequacy in the provision of hospital beds in certain of the invaded districts. The spread of the disease was facilitated by the consequent inevitable delay in removing the patients from their homes, and by the unvaccinated condition of the large proportion of the population. An instance is given of one district in which all the ordinary measures for limiting the spread of the disease were neglected for a long time, with the result that the infection became widespread in eight adjoining districts.

During the year under review small-pox remained mild in type with a low mortality. A few patients became acutely ill before the eruption appeared, delirium being occasionally reported. Instances of grave constitutional disturbance during the second week of the illness were recorded, and in some cases involvement of the eye resulted in permanent impairment of vision. Sir George Newman repeats the conclusion in his previous report to the effect that the present mild epidemic is indistinguishable from small-pox in respect of its clinical character, the protection

afforded by vaccination, its biological reaction, and the potential power of the virus. No vaccinated infants or young children were attacked, although in the days before infantile vaccination small-pox was in the main a disease of childhood. Of 925 cases of small-pox occurring in vaccinated individuals only nine patients had been vaccinated after infancy, and in these nine cases the lapse of time between vaccination and infection was between ten and sixty years. Sir George Newman quotes in this connexion the finding of the final report of the Royal Commission on Vaccination, that immunity could not be assured beyond nine or ten years. In contrast with these figures it is to be noted that a large proportion of the unvaccinated patients were children. Reference is made to the appointment in February of a departmental committee in conjunction with the Medical Research Council with reference to the standardization of vaccine lymph and the improvement of vaccination (BRITISH MEDICAL JOURNAL, February 13th, 1926, p. 294). As a result of the Therapeutic Substances Act, 1925, establishments for the preparation of vaccine lymph will have to be licensed, and the importation of lymph prepared in foreign countries will require to be controlled. The committee will therefore have to advise on the standard requirements and tests to be imposed, and it will also consider whether in certain circumstances advantages could be secured by varying the methods of vaccination—for example, in order to provide temporary immunity during outbreaks of small-pox.

(To be continued.)

## Australia.

### QUARANTINE PRACTICE.

THE Department of Health of the Commonwealth of Australia has issued another of its Service Publications, No. 31 of the series. The latest volume is entitled *Notes on Quarantine Practice for Quarantine Officers*,<sup>1</sup> and the compilation has been entrusted to the safe hands of Dr. Elkington, whose position as chief quarantine officer and experience based on work formerly carried out under the leadership of Dr. Gresswell, and vastly amplified later, are a sufficient warrant for the soundness of the rules laid down, and account for the high place which Australia holds among the foremost of the world's health organizers.

The notes are distributed into eleven chapters, dealing with the subject of quarantine in practically all its aspects—from training the employees in the service how to deal with rat-fleas to the behaviour to be observed by the visiting officer when entering the steward's cabin, nothing seems to have been omitted. The first chapter is introductory, and contains a rapid survey of the quarantine history and legislation from the earlier days when the question began to be considered seriously; this is followed by remarks upon the service itself and the various grades of persons employed in it, their duties, discipline, and so forth. The next chapter deals with the construction and working of ships so far as they affect the quarantine officer. At the end of this chapter, and before starting quarantine matters in real earnest, is a short comic interlude, the officer being instructed, for instance, that "Fanny Adams" means tinned meat, and a "donkey's breakfast" is a mattress (hence, perhaps, this animal's proverbial obstinacy). The following chapters contain very serious reading, dealing in succession with the local quarantine arrangements, the inspection of ships, including the powers and functions of the visiting officer. Next comes a chapter treating of the details to be attended to by the officer in regard to special diseases and suspected persons. The minutiae of active quarantine on ships and at stations occupy two chapters and deal naturally with the duties to be carried out from the point of view of inspection, removal of patients, disinfection, and the necessary reports and returns called for. The chapter on the epidemiology of ships is most interesting, but in our opinion rather unnecessarily detailed. To give one example: few

<sup>1</sup> *Notes on Quarantine Practice for Quarantine Officers*. By J. S. C. Elkington, M.D., D.P.H. Commonwealth of Australia, Department of Health, Service Publication No. 31. Melbourne: H. J. Green, 1925. (6 x 9½, pp. 151.)

quarantine officers, we think, are likely to test a doubtful case of small-pox by Paul's test of inoculating the cornea of a rabbit with the fluid from a pustule, and forty-eight hours later enucleating the eye and examining for opacity in an alcohol-sublimite solution.

The final chapter, on the training of quarantine assistants, shows how very thorough and painstaking that training is, and further, how keen the authorities are that the high standard should be maintained, by making it a rule that every assistant officer should undergo a brief revision course every year. All the important diseases are considered, the possible effects if cases of them should be overlooked, the ways of preventing them, the modes of disinfection and fumigation, the duties of the several officers in their actual quarantine work, and in the filling in of forms, reports, and returns which may be called for.

As the title states, this publication consists of "Notes," and as such fulfils its aim; in fact, there is but one thing needed to enhance its value—namely, an index.

#### MENTAL HOSPITALS IN NEW SOUTH WALES.

The report of the Inspector-General of Mental Hospitals for New South Wales for the year ended June 30th, 1925, has recently been issued. The number of insane persons officially known was 8,265, showing an increase of 120 over the figure of the previous year. The number of admissions during the year was 1,428. Natives of New South Wales formed 60.64 per cent. of the admissions, other Australian States 12.88 per cent., England 14.43 per cent., Ireland 4.90 per cent., Scotland 3.50 per cent., and other countries 3.64 per cent. The number of persons who recovered was 573, equal to a rate of 40.13 per cent. on the admissions and readmissions for the year. Of the 550 deaths during the year, 188 were caused through diseases of the brain: 65 were due to general paralysis, 40 to inflammation and other diseases of the brain, 27 to epilepsy and convulsions, 34 to maniacal and melancholic exhaustion, and 22 to apoplexy and paralysis.

The report comments on the valuable work done by the various reception houses where patients with slight mental disturbances of short duration may secure suitable treatment without the necessity of certification. During the year 1,687 persons were admitted to the reception houses; of these 667 were discharged, and thus avoided certification and removal to a mental hospital.

The Government measures to combat the overcrowded condition of the mental hospitals promise very shortly to bring considerable relief; but more buildings are still urgently needed. The lack of suitable accommodation for the criminal insane has been commented on in previous reports. Attention is again directed to the necessity of providing this accommodation, as the present lack of the requisite buildings causes many persons who should be dealt with in hospitals to remain in prison.

The Inspector-General expresses his dissatisfaction with the lack of provision for mentally defective persons in the State. Other Australian States have passed measures enabling the department to take charge of such persons. The adoption by Parliament of similar measures for New South Wales is strongly urged. A bill designed to deal effectively with mental defectives was drawn up some years ago by the late Dr. Eric Sinclair. Its provisions were founded on the recommendations of the English Royal Commission on the care and control of those classes, but adapted to meet the special conditions of New South Wales. It would have brought under the supervision of the Education Department those mental defectives who were of school age or were likely to benefit by instruction in special schools to be established, and to place the others—that is, those who would not be likely to benefit by instruction and the adolescents and adults—under the control of the Inspector-General of Mental Hospitals. This measure, or some similar measure, is held to be imperative for the welfare of the State, and is demanded by a growing public opinion.

#### ENDOWMENTS BY MEDICAL MEN.

Sir Alexander MacCormick has handed over his private hospital in Sydney, "The Terraces," as a gift to the Presbyterian Church to use as a hospital in whatever form they shall decide. This is a private hospital of some forty

beds, well equipped and established. It is understood that it will be carried on in the future by the Presbyterian Church mainly as an intermediate hospital.

Mr. Gordon Craig, honorary urological surgeon at the Royal Prince Alfred Hospital, Sydney, has endowed a fellowship in urology at the University of Sydney, the clinical work to be carried out at first at the Royal Prince Alfred Hospital. It will be for the purpose of training graduates in the special study of urology, the fellowship to be, in each case, for a period of three years, during which a fellow must undertake clinical work at the Royal Prince Alfred Hospital and research work at a laboratory fitted up and handed over to the University of Sydney by Mr. Gordon Craig. In all, this generous foundation will amount to a sum of £20,000. The clinical work will, for the next five years, be carried out at the Royal Prince Alfred Hospital under the control of Mr. Gordon Craig, who will thus keep an active interest in the scheme, which will naturally be of great assistance in assuring its success.

#### THE LATE SIR CHARLES MACKELLAR.

The death is announced of Sir Charles Kinnaird Mackellar, K.C.M.G., M.B., Ch.M.Glas. Sir Charles Mackellar, besides at one time carrying on a large general practice, was also one of the most prominent of Australian public men. In 1886 he was appointed a member of the Legislative Council, and held the portfolio of Minister for Mines, being at the same time a representative of the Government of the Upper House. In 1903 he was appointed to fill an extraordinary vacancy that occurred in the Federal Senate. The work for which he was best known was that which he did when president of the State Children's Relief Board, where he was able to carry into practice the strong views he entertained as to the reception into institutions of such homeless children; and it was he who, during his fourteen years' tenure of office, carried out an extensive scheme of boarding out neglected children, a method that time has shown to be the most humanitarian. He also was instrumental in the establishment of the Children's Court and small farm homes for delinquent children. It was in recognition of this philanthropic work that a knighthood was conferred upon him in 1916.

## Scotland.

#### VITAL STATISTICS FOR SCOTLAND.

FROM the second quarterly report for 1926 of the Registrar-General for Scotland it appears that the number of births for the quarter, totalling 26,996, is 825 more than that of the previous quarter, although it is 913 less than that of the corresponding quarter for last year. The birth rate of the quarter was 22.1 per 1,000. This is lower than the birth rate of all the second quarters of years since 1855, with the exception of the three war years, 1917-1919. Of the children born, 13,763 were males and 13,233 females. It is pointed out that in England and Wales the quarterly birth rate was 18.7. The number of marriages was 336 less than in the corresponding quarter of last year. The number of deaths registered in Scotland during the quarter was 17,004; this is 924 less than that of the previous quarter, but 1,093 more than that of the corresponding quarter of the previous year, and 205 more than the mean of those of the second quarters of the preceding five years. The quarterly death rate was 13.9 per 1,000. Of the total number of persons dying during the quarter, 3,947, or 20.9 per cent., were children under 5 years of age; 6,959, or 40.9 per cent., were persons between the ages of 5 and 65; and 6,498, or 38.2 per cent., were aged 65 and over. Deaths of children of less than 1 year old numbered 2,158, and as the registered births of the quarter numbered 26,996, these deaths equalled an infantile mortality rate of 80 per 1,000. These infantile deaths were 90 fewer than those of the second quarter of the preceding year and 378 fewer than the mean of the second quarters of the preceding five years. In England and Wales the infantile mortality rate for the quarter was 62, or 18 less than the Scottish rate. Of the 17,004 deaths in Scotland during the quarter, 903, or 5.3 per cent., were due to epidemic

diseases. Of these, the greatest number, 370, were attributed to measles; 175 were due to whooping-cough, 111 to diphtheria, 90 to scarlet fever, and 151 to diarrhoeal diseases. There were 45 deaths from encephalitis lethargica and 27 from cerebro-spinal meningitis, as compared with 39 from the former disease and 23 from the latter during the corresponding quarter of the preceding year. Deaths from influenza numbered 797, as compared with 198 in the corresponding quarter of last year. The number of deaths attributed to tuberculosis was 1,436, which was 74 more than in the previous quarter, but 107 fewer than in the second quarter of last year. Deaths from malignant disease numbered 1,653, which was 27 more than in the previous quarter and 1 more than in the corresponding quarter of last year. Pneumonia accounted for 1,536 deaths, which was 152 fewer than the previous quarter, but 394 more than in the corresponding quarter of last year.

#### DEATH FROM ANTHRAX IN GLASGOW.

A fatal case of anthrax occurred recently in a northern district of Glasgow; investigations by the public health department have not yet definitely ascertained the source of the infection, but it is believed possibly to have been derived from a shaving-brush. Recently a case of anthrax was announced from Manchester as attributable to the use of cheap shaving-brushes imported from Czecho-Slovakia, and the Glasgow authorities withdrew from sale a number of brushes which had been included in the same consignment. These, on bacteriological examination, were found to be free from anthrax spores, but a different type of brush manufactured in the same country revealed anthrax spores in large numbers. The public health department has issued a warning as to the danger of using cheap shaving-brushes. The brushes in question had been retailed at prices varying from 6d. to 9d.

#### ABOLITION OF SLUMS.

At an interview which a deputation from the Slum Abolition League had recently with the Glasgow Presbytery Dr. Robert Forgan, secretary of the League, expressed the hope that the Church of Scotland would form a housing committee. Referring to a recent announcement that the corporation of Glasgow had approved of the erection of another 650 houses, Dr. Forgan remarked that all the houses in contemplation were of a type for people well able to afford a good rent. In order to rescue the slum dwellers from their present horrible conditions and to put them into new environments, houses at a much more reasonable rent were required.

#### CALEDONIAN MEDICAL SOCIETY.

The forty-first annual meeting of the Caledonian Medical Society will be held at Storrs Hall Hotel, Windermere, on Friday, September 24th, at 3 p.m. The annual dinner, at which ladies will be welcomed, takes place on that day; members of the society intending to be present are asked to communicate with Dr. W. E. Henderson, Applethwaite Lodge, Windermere, before September 14th.

## England and Wales.

#### PUBLIC HEALTH IN WALES.

In the seventh annual report of the Ministry of Health for 1925-26 the section relating to the Welsh Board of Health contains interesting details of the progress made in the provision of hospital treatment for maternity cases and for crippled children. The number of municipal maternity homes in Wales is now four, with a total accommodation of thirty-one beds; in addition nineteen local authorities have arrangements with voluntary hospitals for the admission of patients under the maternity and child welfare scheme, and a proposal is under consideration for the establishment of a small maternity home by a voluntary agency in connexion with the scheme for the training of midwives. Two homes for mothers and babies established by voluntary agencies furnish thirty-seven beds for mothers and twenty-nine for infants. There is at present only one home for children under 5 years of age in Wales; this has accom-

modation for fifty. Hospital treatment for crippled children is provided by thirteen local authorities, nine having made arrangements with the Prince of Wales's Hospital at Cardiff, three with the Shropshire Orthopaedic Hospital, and one with the Royal National Orthopaedic Hospital in London. Most of these authorities have also made arrangements to deal with out-patients and to supply after-care treatment. Schemes for the treatment of crippled children are being planned by eight other authorities. In view of the general increased activity in respect of maternity and child welfare several local authorities have found it necessary to increase their whole-time medical staffs.

Although in 1924 there was a slight decrease in the previous progressive decline in the infant death rate, the figure being 77 per 1,000 births, as compared with 74 in the previous year, the rate for 1924 was considerably lower than the rates for the years before 1923. The maternal mortality rate for 1924 was 5.01 per 1,000 births, which, though the lowest for some years, is higher than that for England and Wales combined. The number of stillbirths remains high, the number notified per 100 registered live births having increased from 4.1 in 1921 to 4.7 in 1924; the notification of stillbirths is stated to be probably incomplete. The percentage of the notification of births in 1924 was 94.8, as compared with 91.6 in 1921. The number of visits paid by the 454 health visitors during 1924 to children under 5 years of age was 482,884, an increase of more than 70,000 over 1921; visits were paid to approximately 11,000 expectant mothers. The number of trained midwives practising in Wales increased from 1,439 in 1923 to 1,487 in 1924, and the number of untrained midwives decreased from 509 in the first year to 443 in the year under review. Of the 57,426 births registered in Wales in 1924, about 80 per cent. were notified by midwives, and medical aid was summoned by them in 9,041 cases during the year, which represents an increase of 670 as compared with 1923, and of over 1,600 as compared with 1922. During the year 1925-26 eight new district nursing associations, employing nine trained nurse-midwives, were established; most of these nurses also act as part-time health visitors in rural areas. The number of maternity and child welfare centres in existence on March 31st, 1926, was 243; thirteen of these were provided by voluntary societies and the remainder by local authorities. More than fifty new centres have been established during the last five years, and in several urban areas, owing to the increase in the attendance, additional sessions have had to be arranged. Special ante-natal sessions are now held at nine centres—mainly in the county boroughs—but expectant mothers are encouraged to attend at many other centres. Dental treatment is now provided in connexion with the centres of eleven local authorities, and ophthalmic treatment by six; various minor ailments are dealt with at the centres of seventeen local authorities.

There was an increase in the number of new cases of tuberculosis from 4,794 in 1924 to 5,176 in 1925, due probably to improvement in notification rather than to increased incidence of the disease. On December 31st, 1925, there were on the registers of the medical officers of health 12,364 patients with pulmonary tuberculosis, and 4,514 with non-pulmonary disease; this excludes five sanitary authorities with an estimated total population of 24,000, from which figures have not been received.

All the county and county borough councils in Wales have now made arrangements for the treatment of venereal diseases, and during the year under review two auxiliary centres were opened for the treatment of mothers and infants referred from maternity and child welfare centres. There are now nine approved treatment centres and three auxiliary treatment centres, which work in conjunction with maternity and child welfare centres.

The number of medical practitioners under agreement with the Welsh Insurance Committees has increased from 904 in April, 1925, to 950 in 1926, and the standard of service is stated to be satisfactory. The number of cases referred by approved societies to the regional medical officers during 1925 for examination with regard to capacity for work was 18,325, as compared with 15,108 in the previous year.

# THE ORDER OF ST. JOHN AND THE BRITISH RED CROSS SOCIETY.

Further expansion of the work of the Home Service Ambulance department of the Joint Council of the Order of St. John of Jerusalem and the British Red Cross Society has been found necessary. In the sixth report of the council, which covers the period from April 1st, 1925, to March 31st, 1926, it is stated that the number of ambulances has been increased by ten during the year, and that 76,886 patients were carried, as compared with 70,432 in the previous year. Illustrations are given of the great value of the services rendered by these 351 ambulances and their staffs in saving life and affording quick transport of injured persons to hospitals. Help has been received from the Royal Automobile Club and the Automobile Association. The greater availability of ambulances has, moreover, enabled a larger number of sick persons to be transferred from their residences to nursing homes and hospitals. Throughout the country new divisions and detachments are being established by the two organizations for the provision of training in first aid and nursing which is often centred on the ambulances. In many counties every ambulance is worked by the associated Order and Society, and it is thought that there will be no serious difficulty in completing eventually the process of making the whole ambulance service of the country an integral part of the active peace time work of the two organizations. The ambulances are distributed according to local needs, and are replaced when they are worn out. There was a small diminution in the work of relieving sick and disabled ex-officers, but a slight increase in the number of tuberculous ex-officers who received temporary help while their cases were being investigated by the Ministry of Pensions. Assistance has also been given to some ex-officers whose disability was not considered by the Ministry to be attributable to their military service. Weekly grants for extra diet were made to many tuberculous ex-officers who were undergoing treatment at home as a sequel to residence in sanatoriums. The temporary relief of ex-service men suffering from sickness or disablement attributable to war service has continued, and help has also been provided for widows and dependants. During the year under review 372 grants were made to 62 hospitals and other institutions under the control of the Ministry of Pensions, and various kinds of recreation have been organized for the patients.

## TREATMENT OF SCHOOL CHILDREN AT BRIGHTON.

The report of the school medical officer for the county borough of Brighton for 1925 shows a considerable increase in the number of attendances at the school clinic, though there is a considerable decrease in the numbers of children medically inspected in what are called the code groups of entrants, intermediates, and leavers. The reduction in the numbers in these groups corresponds to the fall in birth rate. The procedure before operation for tonsils and adenoids has been improved by the introduction of more thorough inquiries into the existence in the patient or his surroundings of infectious disease. The after-treatment has also been improved by keeping the children in the sanatorium for one night, and sending them home by ambulance, accompanied by the school nurse. The report contains an interesting account of the case of a partially deaf and dumb boy, who could not be taught in an elementary school, and was certified as fit for teaching and training in the Brighton Deaf School. To this the father appears to have objected; he was summoned and fined on several occasions; but after various shifts and subterfuges for a year his business failed, and he eventually took the boy to the deaf school. As the parent can make no contribution to the boy's maintenance, the committee is waiving any claim for the moment. It seems that under Section 54 of the Education Act, if the authorities are satisfied, after consultation with the parent, that suitable provision for a defective child over 7 years of age is not being made, they may require the parent to send the child to a certified class or school, and the order of a court of summary jurisdiction "shall be a sufficient authority for the conveyance of the child to the class or school named in the order." The Brighton authority finds that there is

doubt about the exact interpretation of the word "conveyance." If it does not mean that the child can be forcibly removed, a parent with the necessary means can ignore the order by paying at intervals statutory fines. In the dental department, out of some 2,000 children leaving school 245 were found to have healthy mouths, and 138 of these had every tooth perfect. It is interesting, perhaps, to compare this position with that of the inhabitants of Tristan da Cunha (as noted in the *BRITISH MEDICAL JOURNAL* of August 28th, p. 399), who appear hardly to clean their teeth at all. However, the school medical officer at Brighton is of opinion that the percentage of healthy mouths in Brighton will increase as the result of periodic inspections and treatment.

## BOURNVILLE: WORK AND PLAY.

Members of the Association who attended the Annual Meeting at Nottingham this year could not have failed to gain some acquaintance with the organization of factories; for Nottingham is a noted centre for great "works." It may be that some of the more curious also saw a few of the lesser factories from beneath whose humble roofs quite excellent work is turned out. Maybe the latter type of works represent the workshops of days gone by and show the transition stage between the independent worker and the factory group. However much we may sigh for the passing of the independent hand worker (yet it is probable that there are more of these than ever to-day), there can be no manner of doubt of the need for great organized industries and for factories if our vast population is to be fed and clothed and housed in an efficient manner. The word "factory" has a bad smell about it, something like the smell of schoolrooms of fifty years ago! But the modern factory is as well kept as the modern school, and it is often no less indicative of life. The decrying of organized work on account of its "monotony" has been somewhat overdone of late, and there is a healthy reaction in the recognition that there is something satisfying in regularity and repetition. These reflections have been stimulated by the receipt of a handsome pamphlet issued by Cadbury Brothers, Ltd., as the *Bournville Annual*. This is a publication started in 1921 with the object of keeping customers informed about some part of the work of cocoa making. Each *Annual* deals specially with some one subject. In past years transport and housing have been described. The latter publication was of particular interest in that it gave a full account of Bournville garden city—a piece of work that the most progressive of civic communities might plume itself upon accomplishing. This year's publication deals with "work and play." The authors, with becoming modesty, suggest that this can hardly be so likely to interest widely as did the earlier publication on housing, but we are inclined to think that this year's subject is of even greater importance. High-pressure organized work differs in one material manner from independent work. The independent worker may go comfortably about his or her work for twelve hours or more at a stretch, just because he is not working all the time; he works as he pleases or as "the spirit moves him." He has no need for the pastimes of leisure, for leisure is taken at many intervals during the work, and perhaps in contemplating it. The worker in organized industries is in a different position; he or she must stick to it without a stop according to the time-table—start promptly, work strenuously, rest for the given interval, begin again, and so on to the end of the working period. A slack worker is ruinously expensive. It follows that the hours of organized work must be short, and there flows from this the problem of leisure—how to fill the unoccupied hours of the day. Nothing to do for a third of the day must be more repugnant than any amount of overwork. Dwellers in Bournville garden city who are gardeners have no lack of occupation. But there are some who cannot dig, and for them and also for the diggers, in Rowheath adjoining there is a sports ground of a size and equipment that must make the mouth of a secretary of any "sports club" water. The recollection of the friendly aspect and beauty of Bournville garden city lasts on from a visit paid during the Birmingham meeting. We have not seen Rowheath,

but the pictures and description of these playing fields and club-houses reserved for Cadbury's workers will make the cocoa and sweetmeats prepared by them still more sweet.

#### STAFFORDSHIRE MENTAL HOSPITALS.

The problems of overcrowding, the necessity of early treatment of mental cases, and the decrease of alcoholism as a factor in the production of mental disorder, are amongst the principal features discussed in the annual reports of Stafford, Brentwood, and Cheddleton Mental Hospitals, issued jointly by the Staffordshire Mental Board. At Brentwood the total number of patients under treatment during the year was 1,104, and the average daily number resident 924, an increase of 22 over the previous year. As there is a ward fewer on the male side than on the female side, the male wards have become inconveniently crowded; and it is hoped that the question of providing further accommodation will receive attention at an early date. At Stafford Mental Hospital only the unusually low admission rate during 1925 has prevented the accommodation being unduly taxed. At Cheddleton the medical superintendent, Dr. W. F. Menzies, discussing the necessity for the establishment of a large colony for mental defectives, points out that such a step would enable the insane patients to have adequate accommodation and treatment. "Overcrowding," says Dr. Menzies, "is bad for the health of the patients, expensive in the fight against communicable infections, trying to the tempers of patients and staff alike, and ultimately expensive to the public, owing to the small but certain percentage who each year should have recovered, but remain chronic for life." The necessity for early treatment is shown by the fact that of the recoveries for the past three years at Stafford Mental Hospital, numbering 211 cases, 55 per cent. were admitted within two weeks of the reported onset of their mental illness, 36 per cent. within three months, and only 9 per cent. after three months had elapsed. At Stafford alcoholism was not found to be so potent a factor in the production of mental disease as in past years. The explanation of its decrease as an etiological factor at Brentwood appears to be partly the result of greater sobriety and partly to the fact that a number of alcoholic cases are being treated to recovery in other hospitals.

#### A CASE OF PLAGUE IN LIVERPOOL.

The Ministry of Health has been notified of the occurrence of a case of bubonic plague in Liverpool. The patient, a boy of 10, became ill on August 27th, and was removed to hospital, where he died on August 30th. The diagnosis of plague has been confirmed by the Ministry's bacteriologist. The boy's father was employed at the docks; he is now in hospital recovering from an illness the symptoms of which are suggestive that he too may have suffered from plague. The remaining members of the household are under supervision and all possible steps to prevent the spread of infection are being taken by the Liverpool Public Health Department. A medical officer of the Ministry is investigating the circumstances.

## Ireland.

#### CENTENARY OF THE COOMBE LYING-IN HOSPITAL, DUBLIN.

AN international congress is being held during the coming week in Dublin to celebrate the completion of the first hundred years of existence of the Coombe Lying-in Hospital, and we mentioned on August 21st (p. 358) some of the outstanding features of the programme. The inception and subsequent history of this institution presents many points of interest. The year 1825 had been one of poverty and sickness, particularly for the impoverished population of the Coombe district, and in the following year came one of those devastating epidemics of fever so common in the eighteenth and nineteenth centuries. The Rotunda was then the only lying-in hospital in the city, and one night two women, struggling towards it from the Coombe, were taken in labour, and next morning were found dead in the snow-covered streets with their new-born infants. In con-

sequence of this a large ward was immediately set apart for obstetrical work in the hospital which John Kirby had established in 1822 in place of the old Meath Hospital, and arrangements were made for attendance on women in their homes. So started the Coombe Lying-in Hospital towards the end of 1826. Expansion followed to meet the great demand, and in 1829 the hospital was reopened as a wholly lying-in institution with thirty-six beds under Richard Reed Gregory as its first master. Gregory, however, died of typhus soon after publishing a report of the hospital in 1830, and the building was closed for eight months, but it then restarted work under Thomas M'Keever. Its existence was soon threatened by an unfortunate dispute with the Rotunda, arising largely out of its status as an educational centre, and for many years its beneficent work was harassed by financial stringency. In 1837 the Duchess of Kent became patroness, and her example was followed in 1864 by the then Princess of Wales. In December, 1851, Benjamin Lee Guinness, Lord Mayor of Dublin, presided over its first public annual meeting, and later gave considerable financial help, which resulted in the provision of more adequate accommodation. In this good work he was succeeded by his son Sir Arthur Guinness, and a new hospital was opened in 1877, since when its progress has been rapid and continuous. In connexion with the centenary a special number of the *Irish Journal of Medical Science* has been issued, and we hope to publish in a later issue a more detailed account of the history of an institution which has battled through to success in spite of a long succession of difficulties and disasters.

#### TUBERCULOSIS IN BELFAST.

Dr. A. Trimble, in his annual report on tuberculosis in Belfast, mentions the poverty and destitution due to unemployment, and describes the attempts made to mitigate the evil. As the census returns were not available, various calculations appear as estimates. The total number of new tuberculous patients was 1,111, the lowest figure since the institution was opened. There were 31,915 re-attendances, and in the case of 216 patients under domiciliary treatment it is stated that the disease had been either apparently cured or become quiescent. The highest tuberculous incidence was found to occur between 7 and 17 years of age, school children furnishing the largest number. Over 41 per cent. of the new patients were living under conditions favouring infection and had been presumably infected; the necessity of personal cleanliness in the household is therefore emphasized. Out of 901 patients definitely diagnosed as tuberculous, only 231 had separate sleeping accommodation. Dr. Trimble continues his series of statistics relating to the effect of tuberculosis on pregnancy, and furnishes the following figures. In the analysis of the end-results of pregnancy it was found that in 2,168 tuberculous mothers 7.9 per cent. miscarried, 89.3 per cent. were delivered of a living child at full term, and 2.8 per cent. of a dead child. Of 1,975 pregnant tuberculous women, 32.9 per cent. improved, 42.3 per cent. remained unaltered, 20.6 per cent. were worse, and 4.2 per cent. died within twelve months of delivery. Dr. Trimble believes that in mild forms of the disease in patients with good environments pregnancy and child-bearing have but little effect on the clinical course of the disease. Details are given of the x-ray, dental, and bacteriological departments, and an account is added of the Calmette, Spahlinger, and sanocrysin treatment, and some observations on the employment of the last named treatment in Belfast. During the year 444 patients were admitted to the municipal sanatorium. On the whole improvement is admitted, but Dr. Trimble insists that much remains to be done.

#### ELECTION OF A MEDICAL OFFICER IN NORTHERN IRELAND.

On August 17th the Enniskillen Board of Guardians considered the appointment of a successor to the late Dr. Moore Betty, F.R.C.S.J., who had been medical officer to the Enniskillen Union Hospital and Fever Hospital for many years. According to the report in the daily press, all the candidates held good degrees; but the supporters of individual candidates openly gave extraordinary reasons for their commendation: one said that on the day of the funeral of Dr. Betty "they" gave a guarantee that they would support Mrs. Betty—that is, support whoever bought

Dr. Betty's practice. This was denied, and a very undesirable argument ensued; the seconder said that he supported the candidate because he had signed an agreement to give up the appointment to young Mr. Betty when he got qualified, and the Bettys were an old and respected Fermanagh family. The supporter of another candidate said that he did so because his candidate was a native of the union, in which the family had been resident for 200 years. In the report in the daily press only one slight reference is made to the experience or qualifications of the candidates. No mention is made of the best candidate or of the best qualified. One may be sure that neither the candidates nor the family of the late Dr. Moore M. Betty are gratified with the efforts, although no doubt kindly meant, of their friends.

#### BELFAST MENTAL HOSPITAL.

The report of the Belfast Mental Hospital for 1925 shows the average daily number of patients was 515 males and 534 females; 219 new patients were admitted. The most prevalent type of disease was melancholia, which affected 28.3 per cent. of the whole of the admissions. Of 139 patients discharged 66 had recovered. An outbreak of typhoid in February, April, and June resulted in two deaths; otherwise the general health was good. The building of one villa for acute cases, one observation villa, one convalescent villa, a residence for the medical superintendent, and a new gate lodge, was commenced during the year, and these additions will be ready for occupation in October: this will provide the much required accommodation for the increasing numbers. The net capitation cost was £34 10s. 2d.: it is the lowest since 1918; and the farm account shows a profit of £2,301. The Ministry's report was highly favourable.

## Correspondence.

#### SANATORIUM TREATMENT.

SIR,—In your review of the statistical inquiry by Messrs. Stocks and Karn into the influence of sanatorium and dispensary treatment and of housing conditions on pulmonary tuberculosis, you do not mention some important fallacies which have not been avoided by the authors.

They come to the conclusion that patients who have dispensary treatment also; and the presumption is that if further progress and of survival than those who have not; and that there is no consistent evidence that bad housing conditions have any influence on the ultimate progress or rate of recovery.

To arrive at reliable conclusions in such an inquiry it is essential to choose similar material in the two groups and to make the difference in treatment mutually exclusive; and neither of these precautions appears to have been taken.

In spite of the statistical safeguards adopted, it is by no means certain that the material was similar in the two groups. Patients are recommended for sanatorium treatment because they specially need it; as far as possible nowadays sanatorium methods are adopted in home and dispensary treatment also; and the presumption is that if patients are sent to a sanatorium the home was unsuitable for such treatment, or the chances of recovery at home less favourable for some other reason. The factors considered by the authors as influencing selection are quite relevant, but they by no means cover the whole ground. Indeed, so many are concerned as to throw doubt on the value of such statistics for the particular purpose: but space precludes further detail here.

Then as regards treatment the two groups are not mutually exclusive. In one we have non-sanatorium treatment which includes a variable proportion of sanatorium methods; in the other, non-sanatorium treatment with stricter sanatorium treatment added for a short time. An average case of pulmonary tuberculosis needs one or two years' treatment. It is exceptional in this country to allot more than from three to five months of the time to sanatorium treatment. This may be sufficient to restore quite early favourable cases to health, but not the majority of those admitted to a sanatorium or applying for treat-

ment. Patients are only exceptionally admitted in a really early stage, and are usually discharged long before the disease is quiescent, the idea being to complete the cure at home with or without dispensary help.

In these circumstances useful conclusions may be drawn as regards the immediate results of treatment; but the later results depend so largely on conditions of life in great variety that it is difficult to institute a fair comparison. Immediate results are usually good, in spite of the handicaps. If relapses happen after leaving the sanatorium, surely the conditions of life are to blame rather than the sanatorium treatment; and conclusions to the contrary from statistics rather suggest that important factors have not been taken into account.

The authors have evidently taken much trouble over their report, which will be of great value, although some of the conclusions are very misleading if taken without further qualification.—I am, etc.,

F. R. WALTERS,

President of the Society of Superintendents  
of Tuberculosis Institutions.

Farnham, Aug. 31st.

#### TUBERCULOSIS AND THE STATE.

SIR,—In the interesting editorial article entitled "Tuberculosis and the State," published on August 21st (p. 349), there are several points which should be of more than passing interest to the tuberculosis officer.

The article itself is indicative of a feeling that things might be better if inquiry was made more into causation, and if effort was directed more towards the establishment of resistance than towards the prevention of infection; in fact, it is almost a challenge to the tuberculosis officer to vindicate his position in society. I am sure that there is nothing which is likely to do so much good as such a challenge.

The criticism that the dispensary system is mainly of statistical value should be answered. The system has been established not only in England but in many other countries. Where there is no definite effort on the part of the State such as exists here, still the dispensary for the supervision of the tuberculous comes into being. Where there is no full co-ordination between the health authorities, the school inspectors, and the medical profession generally, the tuberculosis dispensary exists and remains. The reason for the presence of the dispensary in such countries as Canada and the United States of America is that the sanatorium ultimately demands its existence by asking that the supply of patients may be made up of types which can be established in health. Hitherto it has been possible to find such types only through the agency of the tuberculosis dispensary. The function, indeed, of the dispensary in the long run is the establishment of the type which can exist in that area. It will be seen, therefore, that it is the dispensary which co-ordinates the work done, and in time establishes a close contact with all workers who have to do with tuberculosis.

In 1912 I was instrumental in commencing the dispensary system in Vancouver, British Columbia, and although there was no great enthusiasm at the beginning, within five years so great was the considered value of its work that the general public raised a very large sum to equip an up-to-date clinic for diagnosis and treatment. In fact, it was much easier to raise money for the dispensary system than for the sanatorium. Such was the feeling towards the dispensary system in that district.

Perhaps, however, the dispensary as it exists in England tends to cease to develop clinically, while the development would appear to be initiated by considerations having to do with the infectiveness of the disease.

In your editorial article it is suggested that the dispensary should be made use of more in connexion with such questions as immunization and of generally doing something towards increasing the resistance of the individual against tuberculosis. To go into the question of immunity is to enter into a controversy. What is immunity? Can an individual be established in immunity to tuberculosis in one generation? Is immunization of children a practical proposition? The question is so large and involved that there is room for many points of view.

During the last four years I have endeavoured to solve the question whether immunization could be practised by studying bovine tuberculosis, and I have already published certain conclusions in the *Annals of the Pickett-Thomson Research Laboratory*. I found that tuberculosis in a herd of cattle comes mainly from breeding from immature cattle. If immature cattle are used for breeding, the offspring are more susceptible to infection and to acute massive manifestation of the disease. This is true of both the male and the female. Factors of less importance in etiology are prolonged lactation and inadequate rest. The reason for the lesser importance of these two factors is that the tuberculosis is of a less acute nature and that the animals have a better chance of establishing some degree of resistance. I found that the young apparently sound female which was immature produced the calf most likely to become acutely tuberculous and acutely infective. I found that the mature cow, which reacted to the eye test, was far more likely to have healthy offspring than the immature animal inadequately reared.

It is manifest that decadence, as Aristotle contended, is a stern reality, that events occur in sequence, from the inability of man as a reasoning being to co-ordinate generation and growth.

I came to the conclusion that there is a great deal in immunization, but that to offer immunization only, or to make immunization of a relatively high importance, would be to defeat the end the breeder had in view. I mean by this that if immunization took the breeder away from his old-fashioned conceptions which were definitely eugenic, I could not help him to establish a high-class type which would exist under the conditions involved in commercial farming.

The work of the dispensary system is not merely with the manifestly tuberculous, but by adequate co-operation with all other medical men to collect young people and pick out those who require to be cared for till maturity. It is to use the sanatorium, and by modifying the life and feeding generally to try and give an adequate constitution which may be handed on to the next generation. This work is especially easy in the care of girls before puberty. The main factor in the reduction of the tuberculosis death rate is the more sensible age at which people marry, and that nowadays they breed truer.

The work of the tuberculosis officer is not of a spectacular nature, and unless he has been continuously at the work for a long period he will be apt to grasp at such quicker methods as immunization. I would, however, contend that immunization has a very important place.

The value of the work Sir Robert Philip has done by the introduction of the dispensary system—a system of co-operation with everyone else, a system which has spread widely—is that it is the only system which can help to establish type. His work will be measured by the recognition of the influence of tuberculosis as a factor in civilization.

The tuberculosis officer will retain the conviction that the solution of the tuberculosis question is in the tuberculous. He will continue to regard his patient as a criterion, and when he sees deterioration arising from the infringement of inevitable law, he will tend continually to direct his observations towards the conditions which modify growth and health in the youth of his area.—I am, etc.,

Northallerton, Aug. 23rd.

J. J. THOMSON.

### THE TUBERCULIN DISPENSARY.

(Abridged.)

SIR,—Dr. Camac Wilkinson's letter (p. 967) and your commentary (p. 953) in the *BRITISH MEDICAL JOURNAL* of June 5th will be welcomed by all who have been using tuberculin in ambulatory cases in spite of the "damning with faint praise" of authors and professors who so often refer to the Brompton Hospital Report of the nineties. Sir Almroth Wright's valuable work in 1903-4 reintroduced tuberculin as a valuable remedy in tuberculosis and placed it on a scientific basis. I have used tuberculin since 1906, first as laid down by Sir Almroth Wright, and later following Dr. Camac Wilkinson's method, and can endorse with conviction the latter's opinion, that tuberculin is by far

the best remedy yet known for 75 per cent. of those suffering from tuberculosis and in the type of cases quoted by him, "provided it is given in doses of suitable strength, properly timed, properly administered, and carefully controlled by constant clinical observations."

I quite agree with Dr. Robert Carswell, in your issue of June 12th, when he says that the treatment should be supplemented by every other useful adjunct. It would, however, be difficult in a country like India to give the wage earner complete relief from daily toil; light work would be possible and profitable, but enforced idleness might do more harm than good.—I am, etc.,

C. J. FOX, L.M.S.S.A.Lond.,

Clinical Research Laboratory, Simla, India.

July 29th.

### CRIMINAL RESPONSIBILITY.

SIR,—I have read with interest your leading article (August 28th, p. 392) on criminal responsibility in relation to insanity, and especially dealing with Sir E. Marshall-Hall's able article in the *Sunday Express* of July 25th. As you are aware, this is a subject on which for many years I have been writing, and my opinion of the present law and its effect upon many judges has been brought home to me by practical experience.

I fear there is little chance of the M'Naghten rule being revised, although it is entirely opposed to the present scientific knowledge of mental disease. How can we then alter the paradoxical position by which an insane prisoner is condemned to death in the criminal court, his appeal dismissed by the Criminal Appeal Court, and he is then either handed over to the common hangman or he is sent to the criminal asylum on the report of two medical men who have visited him in the condemned cell and who, under no cross-examination, have put on a piece of foolscap paper their opinion that the condemned prisoner is insane?

I maintain that if we had degrees of murder as in so many other countries this paradoxical condition would not exist.

No one can deny that there are degrees of murder, and yet, if found guilty, the punishment is the same for all. Armstrong, who slowly poisoned his wife; Smith, who drowned his wives in a bath after obtaining possession of their money, assuredly deserved to hang; but are there not many murders committed with no definite "malice aforethought," some on the impulse of some strong emotion and some by persons of definitely weakened intellect and to whom justice could be meted out in the criminal court if the jury were by law able to classify murders in first, second, or third degrees? I believe I am right when I say that almost every murder in which insanity is the only defence would then be placed in either the second or third degree, and the prisoners while serving their sentence in penal servitude, if proved to the satisfaction of the prison medical officer to be insane, could be transferred to the criminal asylum.

I was glad to see recently that the Right Hon. E. Shortt, K.C., late Home Secretary, strongly advocates degrees of murder, the jury to decide in which degree the crime is to be placed, the judge to pronounce sentence.

I fear the statement so often made by judges, that no insane man or woman is now ever sent to the scaffold, is a statement not warranted by facts—known by medical men who have given evidence in these sad cases.—I am, etc.,

LIONEL A. WEATHERLY, M.D.

Bournemouth, Aug. 29th.

### GOITRE IN CHILDHOOD.

SIR,—In the discussion following Dr. Milligan's interesting paper on goitre in childhood, published on August 28th (p. 373) reference was made to the fact that endemic goitre was still very prevalent in Derbyshire, and doubt was cast upon the view by some speakers that it is not diminishing in this county.

A large number of medical men who have practised in this county for many years have told me, both personally and on inquiry, that in their experience endemic goitre has very considerably diminished since they first commenced practice; moreover, the prevailing opinion when many of them commenced was that the disease had for long been

diminishing. Many villages in Derbyshire where goitre was formerly endemic are now goitre-free—for example, Youlgreave and Beeley, to mention only two examples. In places where it formerly existed and where it exists at the present time it is neither so prevalent nor so severe in its endemicity. This diminution is due to improvement of water supplies. I see that Dr. Milligan supports the opinion that pollution of water supplies is, when the evidence is balanced, the likely cause, but McCarrison, in a paper published in April of this year, stated that he had been able to produce in pigeons and rats colloid goitre by the administration of excess lime in the diet over a period of eight months. I have produced goitres in animals by feeding them on cultures of micro-organisms isolated from a water supply in this county, but these goitres were of hyperplastic type and had no resemblance to colloid goitre as seen in adults living in that district. The distribution of goitre in this county shows how closely it is related to places situated either on the carboniferous limestone, or on other geological formations, but deriving their water supply from this formation. In the Ashbourne area goitre was and is still much more frequently seen to the north on the limestone than to the south on the trias. It is likewise much less commonly seen in places deriving their water supply from the millstone grit, of which Buxton is an example. More than one doctor who practises in regions composed of both millstone grit and carboniferous limestone has assured me that goitre is much more commonly seen on the latter than on the gritstone. The view that endemic goitre is seen only in hilly districts far from the sea is not correct. I have observed it to be common in villages to the south of the Lincolnshire wolds, and I am assured by many, well acquainted with the particular district, that it is of frequent occurrence in Bourne. None of these places is far from the sea, neither is any one of them in any sense protected by ranges of high hills from sea breezes.

Information derived from statistics of goitre in childhood alone is misleading; I have observed that many of the slight "goitres" seen so commonly in childhood disappear spontaneously. Goitre statistics based on the examination of school children alone are valueless; and as in many cases the swellings are small and trivial and have no title to be classed as goitre, many observers would miss them altogether. This is undoubtedly the reason for the enormous variation in the incidence of goitre in childhood seen in statistical tables. The incidence of goitre among children in Wirksworth, where it is said to be high, bears no resemblance to the incidence in adults in that area, where it is comparatively low. Moreover, goitre is said to be absent in children in the town of Melton Mowbray, but it is prevalent among adults, and I was recently informed by a practitioner in that town that since the introduction of a new water supply of a very calcareous nature it has increased. There are a large number of women in this county who have very slight and trivial thyroid enlargements, but in many places not more so than I have observed in London or other places which are reputed to be non-goitrous. The majority of these can only be classed as physiological, for they are not seen nearly so commonly after 25 years of age, and in many people are observed during menstruation only. This class of physiological goitre, apparently, has nothing to do with locality, distance from the sea, or water supply; neither can it be said to be in any way related to endemic goitre as I observe it in Derbyshire and in other counties.—I am, etc.,

PHILIP H. J. TUNTON, M.D.

Heanor, Derbyshire, Aug. 31st.

SIR,—In the discussion on goitre in childhood (August 28th, p. 373 et seq.) no reference was made to the possibility that the enlargement of the thyroid is secondary to the commencing of menstrual life in girls. I concluded a good many years ago that there was a very definite connexion. Enlargement of the thyroid is relatively common in girls of about 13, the age when menstruation begins. Dr. Milligan's figures show that goitre is more common in girls, and that it is far more common in girls of 13 years

of age than in younger children. It would be interesting if he would examine the affected children a few years later and note the results. I feel very confident that a large number of the goitres would have disappeared—that is, the enlargement is physiological rather than pathological in a good many cases. Organotherapy is still very largely an unknown field, but all the evidence goes to show that the various ductless glands act and react on one another, and that there is a definite sympathetic interaction between the thyroid and the sexual glands.

I have found enlargement of the thyroid a rarity in boys, but in their case the proper age to look for corresponding signs would be two years later—that is, at about 15 years of age—because the sexual development in boys is about two years later than in girls.

During commencing menstrual life girls are frequently nervous and emotional, and this is probably due to temporary hyperthyroidism. No doubt goitres can be caused by external agents, but the fact that they are found most commonly in girls during a very trying sexual period is suggestive that internal conditions may be an important, if not a fundamental, causative agent in many instances.—I am, etc.,

Birkenhead, Aug. 30th.

D. J. GAIR JOHNSTON.

#### OBSTRUCTION AT THE VESICAL OUTLET AFTER PROSTATECTOMY.

SIR,—Mr. Ainsworth-Davis, in his letter in your issue of July 31st (p. 226), wrote that in his experience perurethral removal of the prostate is "never" followed by contraction, yet in the *JOURNAL* of August 28th (p. 403) he writes that he follows up all cases of prostatectomy, using the cystoscope to anticipate any possibility of post-operative obstruction. If his first statement is correct, routine cystoscopy for the purpose mentioned would appear to be an unnecessary precaution. Passing a cystoscope to determine whether there is contraction at the vesical outlet resembles the use of a sigmoidoscope to detect an anal stricture. Personally I have never experienced any difficulty in finding an opening if the patient can "micturate naturally," in spite of Mr. Ainsworth-Davis's experiences.

Both he and Mr. Loughnane advocate routine packing of the prostatic cavity. I worked under Sir John Thomson Walker and Mr. Pardoe over a period of several years, but cannot remember either of them packing a single uncomplicated case. To adopt such a method indiscriminately is primitive and against all the principles of surgical pathology. An article in the current number of the *British Journal of Surgery* deals with the unsuitability of gauze-packing in these cases.

Mr. Loughnane says that an opening into the bladder can always be seen with the urethroscope, but sometimes there is no opening.

Treatment of contraction after prostatectomy by dilatation is probably as old as the operation itself. Sir John Thomson Walker described the unsatisfactory results of this procedure in the *Lancet* for May 14th, 1921.—I am, etc.,

London, W., Sept. 4th.

W. K. IRWIN.

#### INTESTINAL DIVERTICULA.

SIR,—In the article by Dr. E. I. Spriggs and Mr. O. A. Marxer on intestinal diverticula (*BRITISH MEDICAL JOURNAL*, January 23rd, 1926, p. 130), all diverticula of the small and large intestine are treated as pathological, no matter what their size or etiology, or whether they cause pathological symptoms. No distinction is drawn between the diverticula due to developmental faults and those arising from disease of the potential food pouches, which occur in numbers along the inner wall of the large intestine.

These food pouches or crypto-sacs (if I may be permitted to coin a word from the Greek descriptive of them) are mentioned in my book, *The Ileocaecal Valve* (1914). They are not visible, looking into the bowel during life or after death. The crypto-sacs are caused by the purse-string action of muscular fibres, which, on their contraction, form a pouch or sac, into which semi-fluid faeces are drawn and where they became inspissated. In the living

bowel, through a fistula, their presence is shown by the extrusion of pencils of faeces from the wall of the bowel into the lumen. Before the extrusion of this pencil no sign of an opening was visible, and after the extrusion the bowel wall was quite smooth. The extrusion occurred frequently, when the patient was mentally at ease in the presence of the nurse; but in the presence of the doctor was suppressed, except on rare occasions. The nurse in charge stated that the bowel in the region of the ileo-caecal valve was full of holes, from which faecal pencils were extruded frequently.

The crypto-saks may have their openings closed by disease; the retained contents would then cause trouble by fermentation.

The x-ray photograph No. 10 in the BRITISH MEDICAL JOURNAL article, which is described as diverticula occurring in an otherwise normal bowel, suggests to me a series of these crypto-saks photographed while they contained fluid faeces mixed with barium.

In the future, as series of x-ray plates are taken and studied, they will show whether these crypto-saks occur regularly along the large bowel in the ordinary healthy individual. The evidence brought forward in my book, *The Ileocaecal Valve*, mentioned above, would point to crypto-saks being present along the course of the large bowel.—I am, etc.,

A. H. RUTHERFORD, M.D.Ed.

Sydney, N.S.W., May 18th.

#### LIVE BIRTH.

SIR,—The paper by Dr. Godfrey Carter (August 28th, p. 385) draws very timely attention to the question of infanticide, and, most important of all, the legal definition of live birth.

A full-time normal child, with lungs completely or almost completely aerated and expanded, has lived, and should have survived with proper care; the question whether it was entirely separated from the mother at the moment of death should not be considered. These conditions being found at the *post-mortem* examination should lead to the mother, or other person present at the birth, being put in the witness-box to explain why the child did not survive. There is, however, unfortunately, as can easily be understood, considerable difficulty in finding the mother or person disposing of the body of a dead child, and unhappily these cases of concealment of birth are fairly frequent in big centres.—I am, etc.,

Woodbridge, Aug. 29th.

HOWARD M. STRATFORD.

#### GONGYLONEMA AND CANCER.

SIR,—A paper by Professor R. T. Leiper, entitled "Some observations and reflections on recent attempts to implicate the *Gongylonema* worm in the causation of cancer in man," recently published in the annual report of the British Empire Cancer Campaign (p. 56), contains many references to work of my own on *Gongylonema*. These require some comment. Professor Leiper's remarks may prove misleading to those who have not followed the work which he criticizes. He seems to imply that much of the recent work in which I have had the honour to be associated with Dr. Sambon and the Cancer Field Commission of the Tropical Disease Prevention Association, bearing directly or indirectly upon the problem of cancer causation, is worthless or even pernicious.

My own share in the work, which was mainly concerned with certain districts in Northern Italy, has been the subsidiary one of investigating certain helminthological problems, chiefly concerning nematode worms of the genus *Gongylonema*.

(1) In a paper published in the *Journal of Tropical Medicine and Hygiene*, February 2nd, 1925, I endeavoured to show (among other things) that there was no satisfactory morphological distinction between two alleged "species" of *Gongylonema*—namely, *G. pulchrum* of swine and *G. scutatum* of ruminants. As the former was the earlier name, I proposed that it should be adopted, and *scutatum* be regarded as a synonym. In the same paper I ventured very tentatively to suggest that the *G. neoplasticum* of rats "may perhaps have to be added" to the synonymy of *G. pulchrum*. I was careful, however, to point out

that (in addition to general size, to which I attached less importance) there was an important difference in one character between the two forms, namely, the length (though very variable) of the left spicule of the male. This organ was found not to exceed a length of 0.67 mm. in the specimens of *G. neoplasticum* available, whereas in specimens of the *Gongylonema* of ruminants it varied from 5.0 to 23.0 mm. In view of my inability to fill in the wide gap in these measurements I did not, and do not, feel justified in definitely regarding these two forms as one. My statement meant that, should the gap between them be filled up in the future, then it might perhaps have to be admitted that they were identical.

(2) In another paper in the same journal (October 15th, 1925) I recorded the result of my own examination of certain specimens of *Gongylonema* found in a human being and recorded by Professor Alessandrini of Rome, and stated that in my opinion they were indistinguishable from *G. pulchrum* (using this name, of course, as including *G. scutatum*).

(3) In a joint paper with Dr. Pan and Miss Juliet Sambon in the same journal (December 1st, 1925) I described (among other things) an experiment in which two rats were successfully infected with the *Gongylonema* of ruminants. Inasmuch as the left spicule of a male worm thus obtained measured 4.9 mm. in length, I did not in any way suggest that *G. pulchrum* had, by the change of host, been converted into *G. neoplasticum*. On the contrary, I was at some pains to prove that it had remained *G. pulchrum*.

Turning now to Professor Leiper's treatment of my work, I find that on page 58 of the "Report" he apparently uses my own identification of Professor Alessandrini's human *Gongylonema* as *G. pulchrum* to support the view that the *Gongylonema* occurring in man is not *G. neoplasticum*. On page 60, however, he represents me as believing that the two forms are the same species. Professor Leiper cannot have the argument both ways. Had I really formed a definite opinion that the species were identical, I could not have pretended to differentiate between them in the case of the human specimens.

My mind is still open on the question of the identity of these two forms, as I think is quite clear from all that I have written on the subject. However, Professor Leiper attributes to me a definite opinion in favour of it, and "to determine if there are any real grounds for" my alleged "supposition on the unity of the species," he proceeded to try to carry out the very experiment which I was myself performing—see (3) above—on the infection of rats with the *Gongylonema* of ruminants. In order to do this, while my colleagues and I were already in the Trentino with a grant from the British Empire Cancer Campaign, and without first offering us his valuable assistance, he went independently with Dr. Cameron to Italy, with another grant from the same body, to collect material. Returning to London, he used as intermediate hosts cockroaches from the Zoological Gardens, and was obliged to abandon the experiment on finding that his cockroaches were already naturally infected with the rat-*Gongylonema*. He then reversed the direction of his experiment, and found that he could transmit the rat-*Gongylonema* to sheep. Apart from the fact that *G. neoplasticum* occurs in the London Zoological Gardens, this appears to be Professor Leiper's only constructive contribution to the subject of *Gongylonema* infection, and I had already shown that the converse experiment was possible.

It is difficult, in any case, to see why the correctness of my alleged "supposition" depends on the conversion of typical rat-*Gongylonema* into typical ruminant-*Gongylonema* by a single change of host. Supposing that the species are really distinct, many generations in the new host might reasonably be expected to be required to bring about a definite and recognizable morphological change, and an isolated experiment could hardly throw much light on the question.

Professor Leiper goes on to argue from the result of his own experiment that "it appears probable therefore that the other species, viz., *Gongylonema pulchrum* of the pig, regarded by Baylis as identical with *Gongylonema scutatum* of sheep and cattle, may prove also to be distinct." This conclusion may be "probable," but surely Professor Leiper is not entitled to assume it, as he later apparently does, as an established fact. A recent, and as yet unpublished, experiment of my own has shown that it is not impossible (as appeared likely from an earlier, unsuccessful, attempt) to infect pigs with the *Gongylonema* of ruminants. This, I think, lends no support to the theory of distinctness of species, but tends rather in the

reverse direction. It is, of course, open to Professor Leiper to regard the naturally occurring pig and ruminant forms as separate physiological races or strains—a matter which, so far as I can see, feeding experiments are never likely to settle. But unless he can find some morphological distinction which, for my part, I have failed to detect, he is not on safe ground in asserting that they are distinct species.

Throughout Professor Leiper's paper it appears to be assumed that, as the *Gongylonema* of rats is the only species yet definitely implicated in cancer causation, other extremely closely related species need not be considered. The reason for this assumption is not clear to me. The purely negative statement (p. 60) that "none of the *Gongylonemas* found in domestic stock are associated with the occurrence of cancer in these animals, nor has cancer been observed in any of the cases in which *Gongylonema* has hitherto been recorded in man" may be, up to the present, perfectly true, but it is not conclusive.

Although no evidence is produced by Professor Leiper to prove his contention that *G. pulchrum* and *G. scutatum* are not identical, he propounds some remarkable conclusions, including the following:

(1) That "*Gongylonema pulchrum*" does not occur at Villa Lagarina (cf. p. 59: "Practically all the local cattle slaughtered in this district were found infected with *Gongylonema*"). As Professor Leiper has not investigated Villa Lagarina himself, he is presumably relying upon statements of my own.

(2) That "*G. scutatum*" has not yet been found in man (cf. p. 59: "it is evident that *Gongylonema* in man is the species which normally occurs in pigs").

—I am, etc.,

British Museum (Natural History),  
London, S.W.7, Aug. 19th.

H. A. BAYLIS.

We referred this letter to Professor Leiper, who writes as follows:

SIR,—The reader will be assisted in understanding the above argument if it be made clear that Dr. Baylis differs from other observers, including myself, who regard the gongylonema worms of swine, ruminants, and rodents as belonging to at least three distinct species, named respectively *G. pulchrum*, *G. scutatum*, and *G. neoplasticum*, and has taken the position that *G. scutatum* is merely a synonym of *G. pulchrum*; tentatively—now "very" tentatively—suggesting also that *G. neoplasticum* may have to be added.

Wherever in my report *G. pulchrum* appears it refers to the gongylonema of swine, and *G. scutatum* refers to the gongylonema of ruminants. Applying, however, his own terminological usages (or, as I view them, nomenclatural inexactitudes) to my report, Dr. Baylis arrives, on my behalf, at some "remarkable conclusions." The statement that *G. pulchrum* does not occur in Villa Lagarina, referring obviously to gongylonema of swine, and based upon the failure of the Cancer Field Commission to reveal its presence by an intensive study of the problem in this village, is not invalidated by a further quotation that "practically all the local cattle slaughtered were found infected with *Gongylonema*"; for these cattle harbour *G. scutatum*. Nor is the statement that *G. scutatum* has not yet been found in man—referring, of course, to the gongylonema of cattle—invalidated by a quotation "*Gongylonema* in man is the species which normally occurs in pigs."

Dr. Baylis rightly assumes that I accept the results of his own examination of Alessandrini's material as showing that this gongylonema was merely a case of accidental infection of man with *G. pulchrum* of swine, which was, moreover, as in its normal host, unaccompanied by any cancerous reaction. This determination justifies the conclusion that, so far, "no case of *G. neoplasticum* had been found in man," and thus supports my contention that there is not the slightest scientific foundation for Dr. Sambon's belief that gastric cancer, stated to be very prevalent in certain houses in some villages in northern Italy, is due to invasion with a gongylonema associated with the presence of rats and cockroaches in these so-called "cancer houses."

Dr. Baylis complains that, with a small direct grant from the same body which indirectly but lavishly financed the commission to which he became attached, we tried to carry out the very experiment he was himself performing.

But he has forgotten two points of some interest—namely, (a) these grants were made at the same time (to the knowledge of Dr. Baylis before he left England) with a wisdom and purpose I do not need to concern myself to discuss. (b) The need for such independent investigation arose, not only from his own work, but was actually publicly suggested by him some months previously on two separate occasions in a paper published on February 2nd, 1925. On page 73 he wrote:

"But unless, and until, it can be experimentally proved by those in a position to undertake such investigations [italics are mine] that the form found in one host cannot be transmitted to another host there appears to be no alternative but to regard all these forms as belonging to one and the same species."

And again on page 75, writing on the difficult question as to whether *G. neoplasticum* should be considered a distinct species or not, he remarks:

"It appears to depend upon the importance to be attached to a single character limited to the male sex, viz., the length of the left spicule. Many helminthologists would doubtless consider this quite sufficient to constitute a 'good' species. The writer feels, however, that in view of the amount of variation possible in the forms from other hosts and until a much larger number of males of *G. neoplasticum* has been examined the evidence is rather strongly in favour of specific identity. This view does not, of course, exclude the possibility of the existence of a 'host-race' or even an incipient species confined to rodents. As in the other cases previously discussed, the question calls for careful experimental investigation by those able to undertake it."

Incidentally, it may be remarked that the above gives Dr. Baylis's own words, a précis of which he submits (in the first section of his second paragraph). I will merely ask the reader to compare these two statements.

Although Dr. Baylis claims that we have merely repeated his experiments—the nature of which, by the way, was unknown to us until months later—the purpose in his mind and in ours appears to have been different. That an animal can become infected under experimental conditions although it is never found so infected in nature is a common experience. The fact of successful experimental infection is of somewhat small significance. What is significant is that in the case of *G. neoplasticum* the slight but specific characters remain entirely unchanged, even when the parasite is experimentally reared in sheep. I see no reason to assume that if this species were carried on through several generations in sheep any morphological change should necessarily be in the direction of *G. scutatum*, or to assume that if man became accidentally infected in a rat-infested house the gongylonema found should fail to present the slight peculiarities characteristic of *G. neoplasticum*.

This, as Dr. Baylis affirms, is my chief constructive contribution, but it suffices to warn me against a placid acceptance of his concept of what constitutes a species. Of course, he is fully entitled to his own concepts, and little harm can result from their application to the National Collections. But the acceptance of a ruling, or the adoption of a tentative suggestion concerning the identity of a parasite in different hosts, if one of these hosts be man, is for the medical man not merely an interesting nomenclatural decision. It may raise now and serious problems in the control and prevention of disease. Dr. Baylis does not, apparently, realize the responsibility involved in the publication from the British Museum of an opinion such as the following:

"If, as has been suggested, all these species are identical the fact has very interesting and important bearings upon human pathology." . . . "These domesticated animals—sheep, goats, cattle, and pigs—will have to be considered as important reservoirs of the parasite, and, if Dr. Sambon's theory receives confirmation, as factors in the spread of carcinoma."

Dr. Baylis states that as the gongylonema of rats is the only species yet definitely implicated in cancer causation I appear to assume that other extremely closely related species need not be considered. To this the reply is that until evidence is forthcoming of the association of any species of gongylonema with cancer in man, direct or indirect suggestions that it is so are both worthless and pernicious; for they engender in the public mind false hopes that in the control of the reservoirs and intermediaries of gongylonema lies a solution of the problem of human cancer.—I am, etc.,

London, N.W.11, Sept. 7th.

R. T. LEIPER.

## CORRESPONDENCE.

## MEDICAL DEFENCE.

SIR,—Recent correspondence in the JOURNAL emphasizes—if such emphasis were needed—the unsatisfactory position in which practitioners still find themselves as regards legal protection from attack. Possibly if the North of England Branch had utilized its fullest endeavours at Bath in support of the Warrington and St. Helens recommendation that the Association itself should provide legal protection for its members, we would have been well under way for comprehensive assistance, with a speedy remedy if delay took place.

I would respectfully suggest that at Edinburgh the Divisions of Newcastle and Sunderland should have on the agenda a considered instruction to Council to proceed with an optional scheme forthwith. They will receive strong support from Lancashire.

If pharmacists can receive from their association legal assistance for all difficulties—including even divorce—why cannot the British Medical Association provide similar facilities for its members?—I am, etc.,

JOHN D'EWART.

Manchester, Aug. 30th.

SIR,—Dr. Woods, General Secretary of the London and Counties Medical Protection Society, Ltd., writes (August 28th, p. 405):

"Dr. Murray has evidently not seen my letter which appeared in your issue of April 17th, in which it is explained that this society has for many years protected, and still does protect, its members in respect of locumtenents."

In order to appreciate the true value of this statement in relation to the whole problem it will be necessary to repeat the classification of my last letter.

1. A member of either society may be covered for the acts or omissions.
2. A member of either society may be covered for the acts or omissions of his assistant, locumtenent, house-surgeon, or other subordinate medical officer who is also a member of either society.
3. A member of the Medical Defence Union, Limited, may be covered for the acts or omissions of his locumtenent who is not a member of either society.
4. A member of the London and Counties Medical Protection Society, Limited, will not be covered for the acts or omissions of his locumtenent who is not a member of either society.
5. A member of either society will not be covered for the acts or omissions of an assistant, house-surgeon, or other subordinate medical officer who is not a member of either society.
6. A member of either society will not be covered for the acts or omissions of a nurse or other lay person acting on his instructions.

The question at present being considered is the cover afforded for a locumtenent. There is no dispute about paragraph 2 where the locumtenent is a member of either society.

Paragraph 3 will not be disputed, for the Medical Defence Union, Ltd., made this concession the subject of a special resolution, and the effect of that was published in the BRITISH MEDICAL JOURNAL a few months ago. The whole question arising out of Dr. Woods's letter is one of the truth of paragraph 4. Dr. Woods may rest assured that we have read his letters very carefully and have failed to get any positive evidence that his society has come into line with the Medical Defence Union on the point of covering a principal for the acts or omissions of a locumtenent who is not also a member of either society. I have before me a letter from Dr. Woods, dated February 23rd, 1926, wherein he has very carefully stated the position of his society on several matters, and I will quote the paragraphs relevant to this point.

- "1. That a principal may be held legally responsible for the acts of his assistants or locum."
- "2. That if the principal was a member of a medical defence society and his locum or assistant was not, the defence society would not as a rule defend him on account of the acts of the assistant, but in the case of a locum might defend the principal."

This is Dr. Woods's own explanation of the policy of his society in greater detail than his letter, and there is no evidence that his society has moved from this very uncertain position. So long as these gaps exist in the protection afforded to a member for the acts of his locumtenent so long must paragraph 4 stand as a true statement of the position.

Dr. Woods's letter is quite true, so far as it goes, but does

not give the whole of the case. Let him state in unequivocal terms that his society has come into line with the policy of the Medical Defence Union as set out in paragraph 3, paragraph 4 may then go, and paragraph 3 will apply to both societies. I wish to emphasize the point that Dr. Woods's letter only refers to paragraph 4 of the classification, and the rest stands at this date uncontradicted.

There is a danger that this plain writing may give the societies the impression that we are out on a policy of ruthless destructive criticism. The position is not so. We are all deeply grateful for the help of the societies in the past, and we are now doing our best to get all men to join one or other of the societies. We are anxious that the protection should be complete, and we would much prefer that the old societies should realize the limitations of their present protection and give us what we want. If, however, they absolutely refuse, and persist in trying to persuade us that margarine is butter, we will be forced to go elsewhere.—I am, etc.,

R. H. DIX,  
Honorary Secretary, Sunderland Division,  
British Medical Association.

August 30th.

SIR,—Dr. R. H. Dix's letter in the BRITISH MEDICAL JOURNAL of August 28th (p. 404) gives expression to his dissatisfaction at the present position of medical defence. I think he does not fully appreciate the actual position. According to him a complete and comprehensive cover of the legal liabilities of a doctor arising from the practice of his profession is not afforded by membership of any one of the defence societies. In a certain sense, of course, this is true. No society pays for the preparation of partnership deeds and the like for its members, not to speak of the hire, etc., of motor cars, all of which may be regarded as legal liabilities arising from the practice of the profession. The cover is, I believe, nearly as complete as is practicable, and is, moreover, very much better than if an extended and apparently larger cover was expressed in the terms of a policy. Very many cases which involve heavy expenditure are taken in hand for members of the society which could hardly, by any ingenuity, be brought within the terms of a practicable insurance policy. The discretion possessed by the societies is of greater use in enabling them rather than to decline to defend their members. Dr. Dix says that he and others had thought that "all our burdens" would be borne by the society to which we belonged. This seems to indicate the loose way in which the matter is regarded, as it is out of the question that any society could bear all the burdens of its members, and it would be well if there was some exact definition as to what was intended to be included in "all our burdens."

Dr. Dix gives a categorical statement of the limits he regards as applying to the protection afforded by the societies. The limits which actually exist are given in the memorandums of association of the societies, which are wide enough to cover any protection which anyone well acquainted with the subject would think of being given. As regards the present protection of the societies, Dr. Dix's statement should be altered as follows:

1. A member of either society is covered for his own acts or omissions subject to the articles of association of his society.
2. A member of either society is covered for the acts or omissions of his assistant, locumtenent, house-surgeon, or other subordinate medical officer who is a member of the other society.
3. A member of the Medical Defence Union, Limited, is covered for the acts and omissions of his locumtenent who is not a member of either society.
4. A member of the London and Counties Medical Protection Society, Ltd., is covered for the acts and omissions of his locumtenent who is not a member of either society.
5. A member of either society may, or may not, be covered for the acts or omissions of his assistant, house-surgeon, or other subordinate medical officer who is not a member of either society, at the discretion of the society.
6. A member of either society is, at the discretion of the society, covered for the acts or omissions of a nurse or other lay person acting on his instructions within the scope of the society.

Dr. Dix seems to complain that the societies are not under such compulsion as to compel them to take up every case that comes before them. In the absence of a strictly drawn policy the taking up of cases without any discretion on the part of the councils of the societies would involve

very grave risks of serious disputes and costly litigation, since some members are apt to expect defence in matters that do not at all come within the scope of the societies. Moreover, it would be objectionable for the councils to defend a member who has deliberately persisted in criminal conduct or conduct involving serious legal penalties. I am quite convinced that the discretion which the societies have very wisely given to their councils by their articles of association are altogether in the best interests of the members; not restricting the benefits but greatly extending the scope of the societies.—I am, etc.,

HUGH WOODS,

General Secretary, London and Counties  
Medical Protection Society, Ltd.

London, W.C.2, Sept. 3rd.

#### NOTIFICATION OF PUERPERAL FEVER OR PYREXIA.

SIR,—We have read the article in your issue of August 21st (p. 356) in reference to the Minister of Health's amended regulations relating to the notification of puerperal fever, etc. Whilst agreeing that in the past many cases of uterine sepsis have not been notified, we should like to point out that if cases of pyrexia only are notified a large number of patients with uterine sepsis will go untreated.

After a long experience we are convinced that the cases of sepsis which produce a raised temperature are in the minority. We think that there is another most important sign of sepsis in the early puerperium, and that is the persistence of the red lochia. If attention is not paid to this sign and treated, and if Nature does not do its work, many patients return to hospital for treatment.—We are, etc.,

REMINGTON HOBBS.

MARY R. LEVACK.

St. Mary Abbots Hospital,  
Marloes Road, Kensington, Sept. 4th.

#### SUBACUTE APPENDICITIS.

SIR,—The object of this letter is to stress the fact that there is a subacute insidious form of appendicitis which, independent of any previous appendical storm, does not give rise to any local manifestation, but frequently induces symptoms which point to ulceration of duodenum or stomach. In my experience radiological revision in some cases of this occult form of appendicitis is not reliable in that it not infrequently indicates some gastric perturbation which I find may be compatible with either lesion.

In regard to the diagnosis of this type of appendicitis I know of only one genuine sign: distinct localized pain and tenderness (often accompanied with reflex pains) on deep digital pressure over Munro's point—namely, just at the outer edge of the right rectus muscle in the line passing from umbilicus to anterior iliac spine.

In instances in which similar definite localized pain and tenderness can likewise be elicited on digital palpation in gastric or duodenal areas the diagnosis becomes obvious—a dual lesion, which is quite a common coincidence; the moral is not to omit to examine the appendix when operating for gastric or duodenal ulcers. This treacherous type of appendicitis is constantly associated with obvious inflammation and hypertrophy of the adjoining segment of the ileum, with, as often as not, formation of a deadly dense inflammatory adhesion which binds down the gut in V fashion in the right pelvic dip.

The pathology of this complication does not strain imagination if one briefly visualizes the distribution, and connexion, of the lymphatic vessels of the appendix and ileum, not to add the proofs which have been demonstrated of infection ascending from former to latter. The peristaltic strain involved in forcing material into a caecum bound down by an adherent appendix must necessarily result in some hypertrophy of the muscular coat of the small gut; the discoloration of the involved segment, and nature of adhesions so frequently encountered in the ileo-caecal angle and beneath the last few inches of ileum, clearly indicate infective participation.

For years past I have made it a rule when operating for appendicitis not to quit the abdomen without carefully

inspecting the distal ileum, and have been rewarded by finding, in at least 30 per-cent. of cases, an adhesion, which, if unobserved, would in all probability ultimately have caused acute intestinal obstruction. It is almost superfluous, nowadays, to add that it appertains to the septic past to open any clean abdomen without taking due stock of its contents.

In conclusion, I find the incidence of this subacute form of appendicitis so constantly associated with diseased teeth that I beg leave to repeat the recommendations—(1) have obviously decayed teeth extracted, (2) do not have any tooth filled or crowned without x-ray examination of its roots and socket, and (3) in all cases of diagnostic perplexity, and pains and swelling of the "rheumatic" type, irrespective of an apparently "perfect set," have the teeth x-rayed.—I am, etc.,

Buenos Aires, June 1st.

JOHN O'CONNOR.

#### WEEDS, CANCER, AND ACIDITY.

SIR,—Anent the suggestions of Dr. A. Mackenzie on the above subject, I beg to call attention to the remarks of Joulie with respect to hyperphosphatic and hypophosphatic patients—namely, that he has never met with cancer associated with hyperphosphatic urine as defined by him in his method, and he therefore recommends the examination of the urine, for this condition to be secured, for those who have been operated on for cancer. It is ever the hypophosphatic urine which is associated with cancer.—I am, etc.,

London, S.E.24, Aug. 29th.

J. BARKER SMITH, L.R.C.P.

#### Universities and Colleges.

##### UNIVERSITY OF CAPE TOWN.

At the graduation ceremony held in July the following were admitted to the degrees of M.B., Ch.B.:

S. Goodman, S. S. Hoffmann, J. Hotz, J. I. Lipschitz, B.A., W. Milne Murray.

#### The Services.

##### KING'S HONORARY SURGEON.

THE KING has been graciously pleased to approve of the appointment of Colonel Frederic Hibbert Westmacott, C.B.E., T.D., F.R.C.S., Assistant Director of Medical Services, 42nd (East Lancs) Division, T.A., to be Honorary Surgeon to His Majesty, in succession to Colonel E. C. Montgomery-Smith, C.M.G., D.S.O., T.D., M.D., retired.

##### BLANE MEDAL.

SURGEON LIEUTENANT COMMANDER STEWART R. JOHNSTON, R.N., has been awarded Sir Gilbert Blane's Gold Medal, he having obtained a first-class certificate at the examinations held in 1926 for promotion to the rank of surgeon commander.

##### DEATHS IN THE SERVICES.

Lieut.-Colonel Walter Frederick Hamilton Vaughan, R.A.M.C. (ret.), died at Bridgwater on August 26th, aged 47. He was born on March 1st, 1879, the son of W. Filmer Vaughan, Esq., educated at St. Mary's, and took the M.R.C.S. and L.R.C.P. Lond. in 1901. After acting as resident senior medical assistant at Marylebone Infirmary, Notting Hill, and as clinical assistant at Leicester Infirmary, he entered the R.A.M.C. as lieutenant on January 30th, 1904, and became major on July 1st, 1915. He was placed on half-pay, on account of ill health, on August 9th, 1920, and in his subsequent retirement was granted the rank of lieutenant-colonel.

Lieut.-Colonel John Oldfield Greatrakes Sandiford, R.A.M.C. (ret.), died on July 11th. He was born on May 11th, 1854, educated at Queen's College, Cork, and graduated M.D. and M.Ch. in the Queen's University, Ireland, in 1877; he took the L.A.H. (Dubl.) in the same year. He entered the army as surgeon in 1880, became lieutenant-colonel after twenty years' service, and retired in 1901.

Surgeon Captain John Charles Grosart Reed, R.N. (ret.), died at Salisbury on August 2nd, aged 53. He was educated at Guy's, and took the diplomas of M.R.C.S. and L.R.C.P. Lond. in 1895. He entered the navy in May of that year, became staff surgeon in May, 1912, and retired in 1923, with an honorary step in rank as surgeon captain. He served in the China war of 1900 as surgeon of H.M.S. *Algerine*, when he was present at the capture of the Taku Forts and the relief of Tientsin (medal with clasp). When the recent war began in 1914 he was serving at Bermuda, but during the last two years of the war was senior medical officer of the battleship *Exeter*, in the Grand Fleet.

## Obituary.

JOHN GEORGE ADAMI, C.B.E., M.D., F.R.S.,  
F.R.C.P., F.R.C.S., Hon. D.Sc., LL.D.,

Vice-Chancellor of the University of Liverpool; late Strathcona  
Professor of Pathology, McGill University, Montreal.

THE death of Dr. J. G. Adami on August 29th removes one who played a prominent part in pathology and medical education.

Coming originally of Italian descent, his ancestors had for several generations been medical men, but not his father. John George Adami, the fifth child and eldest surviving son, was born on January 12th, 1862, at Manchester, and had the same christian names as his father; his mother, Sarah Ann Ellis Leech, daughter of Thomas Leech of Urmston, Lancashire, was a sister of Dr. Daniel John Leech (1840-1900), professor of materia medica and therapeutics in the Victoria University and physician to the Manchester Royal Infirmary. The Adami family lived in Manchester and Ashton-upon-Mersey, and George received his early education at Owens College. His medical life may be divided into four periods: the first in Cambridge, as undergraduate, demonstrator of pathology, and John Lucas Walker Student in Pathology (1880-92); the second in Montreal as professor of pathology (1892-1914); the third when, during the war, he served with the Canadian Army Medical Corps in Europe (1915-18); and the fourth when he was vice-chancellor of the University of Liverpool (1919-26).

Adami went up to Christ's College, Cambridge, in 1880 at the same time as his lifelong friend Arthur Everett Shipley, Master of the College since 1910, to whom he dedicated his *Principles of Pathology* in two volumes. He was a scholar and Darwin prizeman (1885) of the College, and in 1920 was elected an Honorary Fellow. As an undergraduate he was an active member of the Cambridge University Natural Science Club, being elected on August 6th, 1881, at the same time as A. E. Shipley; he read three papers—on "Rudiments in man," "The thymus," and "Medical degrees"—before he took his degree. He obtained a first class in Parts I and II of the natural sciences tripos in 1882 and 1884, taking physiology as his subject in the second part, and being in both years in the same class as A. E. Shipley and Henry Head. W. Bateson and Sherrington were a year senior to him, so there were giants in his time. He then worked for eight months at Breslau in Heidenhain's laboratory on the blood supply of the frog's kidney, and by careful experiments showed that it was impossible by ligaturing the renal artery to deprive the glomeruli of blood (*Journ. Physiol.*, Cambridge, 1885, vi, 382), thus controverting Nussbaum's earlier statement. After doing his clinical work at Manchester, where he was under the eye of his uncle, the late Dr. D. J. Leech, and being house-physician for six months at the Manchester Royal Infirmary under Drs. Morgan, Dreschfeld, and Ross, he returned to Cambridge in April, 1888, as demonstrator of pathology to Professor C. S. Roy, following, after a short interregnum,

Sir Almroth Wright, who had held this post for a brief period. With Roy, a disciple of Cohnheim and a genius in experimental work on the border-line between physiology and pathology, he did a large amount of research on the cardio-vascular system, as is shown by a series of contributions, such as the opening paper in the Pathological Section at the Glasgow meeting of the British Medical Association, on "Failure of the heart from overstrain" (*BRITISH MEDICAL JOURNAL*, 1888, ii, 1321). In this communication reference was appropriately made to the observations of Clifford Allbutt, who at this meeting delivered the address in medicine, on his own sensations when overcome in the Alps. Roy and Adami wrote:

"Of acute overstrain of the heart from intense muscular exertion, one of us (R.) has on one occasion had personal experience: when, during convalescence from typhoid, he found himself called upon as a medical man to make a fatiguing and rapid journey over the Mer-de-Glace to the 'Jardin' to attend to a Chamouni guide. . . . The sensations felt were well described by Clifford Allbutt, with those observations on overstrain of the heart our own results fully coincide. . . . With regard to the objective phenomena, it did not occur to the one of us personally involved in this matter to percuss out his heart, as was done by the more intelligent Clifford Allbutt, who found the area of dullness increased; but such characteristics of the condition as are appreciable to the non-medical eye led the injured guide in question to remark 'Mais vous êtes essouffé, Monsieur, il faut prendre du cognac.'"

This short excursus is perhaps admissible from its interest concerning three distinguished teachers in the university, although Allbutt was not to take up his work there until 1892. This paper, like those in the *Practitioner* (1890, xlv and xlv), the *JOURNAL* (1892, i, 455), and the more detailed memoirs in the *Philosophical Transactions* (1893, clxxxiii, 199-298), and *Proceedings of the Royal Society* (1891-92, 1, 435), contained a number of tracings. Adami, however, was busy in other directions besides teaching and collaborating with Roy; he wrote on the functions of the glomeruli of the kidney and albuminuria (*Practitioner*, 1889, xliii, 241), and in 1889 had a curious experience which might have been very

serious, as he related in "Notes on an epizootic of rabies with a personal experience of M. Pasteur's treatment" (*BRITISH MEDICAL JOURNAL*, 1889, ii, 808). In investigating an epidemic rapidly killing off the fallow deer in Ickworth Park, which had been assumed to be anthrax but was subsequently shown to be rabies (*Ann. Inst. Pasteur*, Paris, 1889, iii, 658), he cut his finger during a necropsy on a deer; though thinking little of this accident, he went, on the urgent advice of Roy, to the Pasteur Institute in Paris for treatment, and then began to suffer from insomnia, depression, tingling in the limbs, and finally from difficulty in swallowing. Of the two alternatives—an abortive attack of hydrophobia or a nervous condition due to auto-suggestion—he inclined to the second interpretation. In 1890 he was appointed John Lucas Walker Student in Pathology, and, continuing his experimental work, brought out a number of shorter papers—for example, on pseudo-tuberculosis due to a minute nematode (*Med. Chron.*, Manchester, 1890-91, xii, 466), on immunity (*ibid.*, 1891-92, xv, 95, 151), and on the variability of bacteria and the development of races (*ibid.*, 1892, xvi, 366), a subject he returned to on several occasions.

Photograph by

J. GEORGE ADAMI, C.B.E., M.D., F.R.S.

[Lafayette, Manchester.

He worked for a time at the Pasteur Institute, but returned to Cambridge on being elected a Fellow of Jesus College in 1891, and, having taken the degrees of M.A. (1888) and M.B. (1889), proceeded to that of M.D. in 1892.

In the autumn of 1892 he went to Montreal as Strathcona Professor of Pathology in McGill University, and at once became most actively engaged in teaching, leading, and research in pathology, and continued to do so until after the outbreak of war in 1914; he did not, however, actually resign the post till 1919. In Montreal he was engaged in organizing the university department and directing the necropsies at the Royal Victoria Hospital, and his energies were wisely and widely directed on the broadest lines; he encouraged his pupils and others to do original work in his laboratories, among them being Professors O. Klotz and C. W. Duval, W. W. Ford, G. A. Charlton, and Maude E. Abbott. There was thus a continuous stream of papers from his laboratory dealing with all branches of pathology and its application to other sciences as well as to practice—for example, such diverse subjects as Picton cattle disease, hepatic cirrhosis, subinfection, the relationship between inflammation and sundry forms of fibrosis (Middleton-Goldsmith Lectures, 1896, Pathological Society, New York), the classification of tumours, retroperitoneal lipomas, exogenous ulceration of the intestines, tuberculosis, myelins (with Professor L. Aschoff of Marburg), heredity of disease, eugenics, town planning, and child welfare. The position he attained is shown by some of the high offices he held; he was president of the Royal Society of Canada (1912), an honour which had not previously been conferred on a pathologist, of the Association of American Physicians (1912), and of the Canadian Association for the Prevention of Tuberculosis (1909-12). After the death of Professor A. A. Kanthack in December, 1898, Adami was obviously the ideal successor to the chair of pathology at Cambridge, and his university friends made this known to him in no uncertain terms. There can

be no doubt that had he consulted his own wishes he would most gladly have come back, but almost at the last moment unselfish considerations made him withdraw his candidature, and he remained at Montreal, though he was not free from temptations to go elsewhere. He was President of the Section of Pathology and Bacteriology at the Ipswich Meeting of the British Medical Association in 1900.

With the outbreak of war he enthusiastically gave his services unreservedly to this country, and received a temporary commission as colonel C.A.M.C. and Assistant Director of Medical Services in Charge of Records, with headquarters in London. In 1918 he wrote a very readable work, the first volume of *The War Story of the Canadian Army Medical Corps*, which brought the history down to the autumn of 1915, and recorded the outbreak of cerebrospinal fever among the troops on Salisbury Plain soon after their arrival in 1914, and the events during the second battle of Ypres. *The Bulletin of the Canadian Army Medical Corps* (March, 1918, to May, 1919) bears evidence of his activities in articles on the presence of diphtheria and diphtheroid bacilli in wounds, and a detailed report of the enemy air raids upon Canadian hospitals. In 1917

the Medical Research Committee appointed a special committee to report on the standardization of routine pathological methods, consisting of J. G. Adami, Dr. (now Sir) F. W. Andrewes, and Professor W. Bulloch; this committee, of which Adami was the first chairman, was responsible for reports on the Wassermann reaction, the detection of spirochaetes, the laboratory diagnosis of gonococcal infections, and the reaction of media.

In June, 1919, the council of the University of Liverpool unanimously elected him vice-chancellor in the place of Sir Alfred Dale, and he keenly threw himself into the manifold duties of this last phase of a life full of successful endeavour. Entering thoroughly into the routine duties, the social life, and educational problems of all sorts, he was very active on the Consultative Committee of the Board of Education, particularly in connexion with the report on the differentiation of curricula between the

sexes in secondary schools (1923), and the report of the inspectors on the visitation of the medical schools of the University of London (1924). In 1923 he had been appointed inspector for the intermediate and final subjects and had as his colleague for the preliminary medical studies Dr. George Senter, Principal of Birkbeck College. Adami carried through the task, which might, in other hands, have been difficult and delicate, of inquiring into the doings and domestic details of the medical school with tact and sympathy for their post-war difficulties and wrote an admirable report balancing the relative claims of the large and small schools. But with all this he did not lose touch with his old love pathology, and was active at the Liverpool Medical Institute reading papers on the diphtheroid group of organisms (1920), in which he had taken much interest during the war, on the pathology of influenza (1921), and critically set out the difficulties in accepting Dr. James Young's cancer parasito with a complex life cycle (1925). Before the

full survey of the 1918 pandemic, which he had completed two years before but had not then been published.

His great work, *Principles of Pathology*, came out in two volumes, the first on general pathology (pp. 948) in 1909, and the second dealing with special pathology (pp. 1,082), in which he was assisted by Dr. A. G. Nicholls, in 1910, and met with such a cordial reception that a second edition was published in 1910 and 1911. As these two bulky volumes covered more ground than the average student could be expected to master, an admirable *Text-Book of Pathology* (pp. 759) was brought out to meet his needs in 1912 by Adami and the late John McCrae, and rapidly passed into a revised and enlarged second edition (pp. 879) in 1914. A very important piece of work was his article on inflammation in Allbutt's *System of Medicine* (1896, i, 54-139), which was considerably expanded in the second edition of this *System* (1905, i, 702-818), and published separately by Macmillans, passing into a fourth edition (pp. 254) in 1909. In this monograph the wide knowledge of biology and the kindred sciences, for which his Cambridge training was responsible, was obvious. His contribution on inheritance

and disease to the first edition of Osler and McCrae's *Modern Medicine* (1907, i, 17-50) was a valuable summary of a subject of which he had long taken an independent view, and to which he returned ten years later in his Croonian Lectures before the Royal College of Physicians of London. In the second and the present third edition of this *System*, which were cut down to a smaller bulk, Adami's article, together with other general articles, was sacrificed. He became a Member of the Royal College of Physicians of London in 1910 and a Fellow in 1915; he gave the Croonian Lectures in 1917 on "Adaptation and disease," in which he argued with much skill and many illustrations against the biological doctrine that acquired characters are not transmitted; he thus became involved in a rather vigorous controversy with Sir E. Ray Lankester. These lectures, under the title *Medical Contributions to the Theory of Evolution*, were, with a number of previously published papers dating back to 1892, brought out the following year in a book which was reviewed in the *JOURNAL* (1918, i, 619) by the late Sir William Bayliss.

Both as a writer and a speaker Adami had a graceful and attractive style, and, whatever the actual truth may have been, they seemed, especially speaking, to come easily and without the effort that most of us experience, for he had a light hand and a saving grace of humour. As has been shown, he covered a very wide field and was much in request, particularly in his Canadian period, for addresses. He was very happy in his biographical and historical essays—for example, in "The Edinburgh tradition" (1900); "Sir John Harington" (1908); "A great teacher (Sir Michael Foster) and his influence" (1910); "Charles White of Manchester (1728-1813) and the arrest of puerperal fever," the Lloyd Roberts Lecture, Manchester Royal Infirmary, 1921; and his two articles in the recent Memorial Number of the *Bulletin* of the International Association of Medical Museums (1926) on Sir William Osler, that entitled "Last days" being particularly fine in feeling and human touch.

While the most optimistic and genial of men and never speaking evil of others, he was very independent, was no mean fighter, and spoke out fearlessly when he felt it his duty, as was shown by his address on venereal disease among the dominion and colonial troops entitled "The policy of the ostrich" (*BRITISH MEDICAL JOURNAL*, 1919, i, 98). He was always extremely open-minded in investigating any new idea which might be brought to his notice, and in sympathetically encouraging research of any promising point, especially when support was not freely forthcoming elsewhere. Thus in 1916 he pleaded generously for more consideration and recognition of the late E. C. Hort's work and conception of the complex life cycle of bacteria, and more recently he supported and supervised Dr. W. Blair Bell's views on cancer and the treatment by lead. He indeed intended, on his retirement next year from the vice-chancellorship on account of the age limit of 65, to devote his energies to the latter subject.

He had many outside interests, especially in art and music; he had an extensive knowledge of Continental picture galleries, had exhibited his own water-colours, made fine collections of drawings and china, and composed an anthem, "Lighten our darkness." In 1924 he wrote for the Anglican Evangelical Group Movement a pamphlet (No. 51), "The unity of faith and science."

Numerous honours came to him; he was elected F.R.S. in 1905 and was subsequently on the council, he was awarded the C.B.E. for his war services in 1919, was an LL.D. of three universities, and received the honorary D.Sc. on the celebration of the bicentenary of Trinity College, Dublin, in 1912. He was created a Fellow of the Royal College of Surgeons of England (1919), and an Honorary Fellow of both Jesus and Christ's Colleges, Cambridge, in 1920. The Medical Society of London awarded him the Fothergillian Gold Medal in 1914.

For more than two years he had courageously fought the progress of a disease of which he, more than most medical men, must have known the inevitable end, and with ups and more downs in its course, had successfully carried on his work almost to the end. He took an active part at the Cambridge meeting of the universities of the British Empire, July 12th to 16th, and on July 23rd opened the

discussion, in the place of Dr. W. Blair Bell, who was ill, on the nature of malignant neoplasia and their treatment with lead, in the Section of Medicine at the British Medical Association meeting at Nottingham. It will be remembered that at the rather animated discussion of the treatment of malignant disease by lead at the Medical Society of London on March 22nd last, he was prominent in presenting the work done by the team of experts engaged on this research at Liverpool. After the Nottingham meeting he rapidly went down hill and died peacefully at 6.30 p.m. on Sunday, August 29th. He was twice married; to his devoted wife, his daughter, and son the deep sympathy of the profession which he served so long and devotedly will go out.

HUMPHRY ROLLESTON.

#### OUR LIVERPOOL CORRESPONDENT writes:

The medical profession in Liverpool was justly proud that the vice-chancellorship should be held by a medical man; he was well known to the profession, and on intimate terms with many of its members. His advent to the high office was signalized by a strenuous endeavour to improve the finances of the university. With this object Dr. Adami enlisted the services of the civic authorities, and at all times insisted on the importance of town and gown being united in every good object. He never lost sight of the importance of the university motto—"Haec otia studia forent." He felt it to be his duty, not only to promote efficiency in the university, but to show that sound knowledge was the basis of human happiness in every path of life. In his multifarious engagements the progress of the university was ever uppermost, and in his addresses at public meetings Dr. Adami always left with his hearers some facts to ponder over. He was a convinced believer in "mens sana in corpore sano," and rather deplored that the students did not take more interest in athletics and physical exercises. He was a great favourite with the students and thoroughly entered into their amusements. He will indeed be sorely missed by the academic youth. As a man Dr. Adami was genial and affable in no slight degree, ready with a quip if occasion offered, and broadminded in his outlook on the world. His after-dinner speeches were always good. He enjoyed life, and always gave the impression that he desired others to do so too. Dr. Adami was an enthusiast in what he undertook, and infected others with a like feeling. We feel in Liverpool that a great light has gone out, a man full of energy has been removed from our midst. Dr. Adami will be indeed missed, not only by the students but by all classes of the community. He was an example of indefatigable energy: "Whatsoever thy hand findeth to do, do it with thy might" might be said to have been his guiding principle.

The funeral service took place on September 2nd at the Cathedral Church of Christ, Liverpool, when the Bishop of Liverpool (the Right Rev. A. A. David, D.D.) gave an eloquent appreciation of the late Vice-chancellor; the interment at Allerton cemetery followed. The university and city will attend a memorial service at the beginning of the Michaelmas term.

The funeral service in the cathedral was most impressive. Its note throughout was one of gratitude for a noble life and eternal hope for all those present. The large congregation contained representatives of the university, the civic authorities, educational establishments, and social and philanthropic institutions. Lord Derby, as chancellor, headed the university representation; the Lord Mayor, accompanied by the leading city officials and merchants, represented the city; and the mayors of several neighbouring municipalities also attended. The Bishop, in his address, touched upon the character and intellect of Dr. Adami. His note was one of praise and thankfulness for that gallant spirit kept bright and high, undimmed by weariness and suffering. To his great gifts of intellectual grasp and penetration, of fine courage in the quest of truth, Dr. Adami added his knowledge and love of man. He saw the best in men and believed in it. That was the secret of the vice-chancellor's happiness and his influence over those with whom he came into contact. The service

was expressive of such thoughts, and the whole congregation was sensible of the beautiful and solemn dignity in which it was executed. The organ was played by the cathedral master of the music, Mr. Goss-Custard. During the assembly of the congregation Chopin's *Marche Funèbre* was played, and the hymns chosen had a dominant note of praise and were exquisitely rendered by the choir.

#### JOHN HOWARD MUMMERY, C.B.E., F.R.C.S.,

Past-President, British Dental Association.

We regret to record the death of Mr. John Howard Mummery, at the age of 79, after a short illness.

Mr. Mummery was the son of a dentist, and early cultivated an interest in dental microscopy. He received his medical and dental education at University College Hospital, and obtained the diplomas M.R.C.S.Eng. in 1870 and the L.D.S. in 1873. He was awarded the honour of election as F.R.C.S. in 1923 as a member of twenty years' standing. In recognition of his distinguished services during the war in connexion with injuries of the jaw he received the C.B.E.; the University of Pennsylvania had previously conferred upon him the honorary degree D.Sc. in 1915. He was president of the Odontological Society of Great Britain in 1892, and again in 1908 when the society was incorporated with the Royal Society of Medicine as its Odontological Section. He had held office as president of both the British Dental Association and of the sixth International Dental Congress in London in 1914. He served on the committee appointed by the Medical Research Council for the investigation of dental disease. In 1922 he was awarded the Miller Prize of the International Dental Federation for original scientific research in dental histology.

Mr. Mummery combined a keen interest in scientific research with a literary ability which enabled him to communicate his discoveries freely to others. After a long and patient investigation of dentine he was able to show that it was abundantly supplied with nerve fibres; while his recognition of the importance of comparative morphology combined with embryology in dental science enabled him to make discoveries which won him an international reputation. Advancing years brought with them no diminution of energy, and at the age of 72 he published a book on the microscopical and general anatomy of the teeth, which almost at once became a classic. He contributed numerous papers to the *Philosophic Transactions* of the Royal Society, and within the last two months two important articles by him were published in the *British Dental Journal*.

To his wisdom he added a warm affection for his colleagues and a keen interest in the work of younger investigators in dental anatomy. He spent himself freely in the service of his friends and in devotion to dental science; his loss will be mourned deeply and widely.

Dr. HUBERT TEMPLER DEPREE died in a nursing home at Exeter, after a short illness, on August 30th; his sudden end came as a great shock to his relatives and to all who knew him in the various stages of his career. He was born in 1885, and was educated at Clifton College, where his musical genius was soon recognized. He won the Organ Scholarship at Clare College, Cambridge, but elected to study for the medical profession; he was a prominent member of the University Musical Society, and his skill as a pianist and accompanist was in great demand at concerts and "smokers." On leaving Cambridge he obtained the Organ Scholarship at Guy's Hospital, where his natural aptitude for clinical medicine and surgery was at once evident; he was recognized by his teachers as exceptionally brilliant. He possessed to an extraordinary degree the faculty of absorbing the bedside teaching of the registrars and clinical staff, and this, combined with a rare clinical instinct and an almost devastating common sense, reduced the need of laborious textbook study. He obtained the diplomas M.R.C.S., L.R.C.P. in 1911, and graduated M.B., B.Ch.Camb. in the following year. After holding house

appointments at Guy's, and being house-physician to the late Dr. Lauriston Shaw, he went to St. Mary's Hospital as resident anaesthetist, and later returned to Guy's as a staff anaesthetist. On the outbreak of war he immediately joined up as a naval surgeon. After the war he resigned his post at Guy's and entered general practice in Exeter, where he became honorary anaesthetist to the Royal Devon and Exeter Hospital and surgeon to the Exeter Dispensary. He married Miss Lilian Willey, and leaves one son and two daughters. In accordance with his wish, repeatedly expressed, he was buried at sea off the Devonshire coast on September 2nd, a memorial service being held at the same time in Exeter Cathedral.

Dr. JAMES GLOVER, who died from chronic diabetes at Barcelona on August 26th, received his medical education at Glasgow, where he graduated M.B., Ch.B. in 1903. After holding the posts of assistant surgeon to the Eye, Ear, and Throat Free Hospital, Cheltenham, and senior assistant tuberculosis officer to the Royal Hospital for Diseases of the Chest, he spent some years in South America; on his return to England he took part in founding the Psychotherapeutic Clinic in Brunswick Square, London, and was its director until it ceased work in 1922. He spent a considerable time at Berlin studying psycho-analysis under the late Dr. Karl Abraham. At the time of his death Dr. Glover was a member of the council of the British Psycho-Analytical Society, and chairman of the Medical Section of the British Psychological Society. He gave great assistance in the preliminary organization of the London Clinic of Psycho-Analysis which is about to be opened, and had recently been appointed assistant director of it. Dr. Ernest Jones writes: Modest and retiring by nature, James Glover was not widely known in the profession, though his valuable qualities were rapidly compelling increasing recognition. By a small circle, however, he was already recognized as a man of quite unusual gifts. He possessed insight of the highest order into psychological problems, combined with remarkable sagacity and shrewdness of judgement. He was unsurpassed as a practitioner of the psycho-analytic method of treatment. He would easily rank among the first half-dozen psycho-analysts in Europe. His contributions to medical literature, all of a highly technical nature, are mostly contained in the *International Journal of Psycho-Analysis* and the *British Journal of Medical Psychology*. James Glover's death, at the early age of 42, has removed one of the most accomplished figures in a difficult branch of medical research. There is little doubt that had he lived he would in ten years' time have been widely recognized as a worker of commanding importance in this sphere of psychopathology.

Dr. CHARLES VANCE SMITH, who recently died while taking a holiday on the Continent, received his medical education at Sydney University, where he graduated M.B., Ch.M. in 1924. He came to England in the autumn of the same year and engaged in post-graduate work; afterwards he was temporarily attached to the Croydon General Hospital, and held appointments also at the Essex County Hospital, Colchester, and the West Kent General Hospital. A colleague writes: Dr. Smith's bright nature made many friends, and the deepest sympathy is felt with his parents in New South Wales.

The death took place at Turnberry on August 23rd of Dr. S. J. MOORE, a well known practitioner in the west end of Glasgow. Dr. Moore was educated at Glasgow High School and at the University of Glasgow, where he graduated M.B., Ch.B. in 1901 and took the M.D. degree in 1919. Dr. Moore, together with his wife, Mrs. Mary Theresa Moore, who was also a graduate of Glasgow University, took special interest in the diseases of children, and they held appointments as physicians to out-patients at the Royal Hospital for Sick Children in Glasgow. During the war Dr. Moore served as a temporary captain in the R.A.M.C.

## Medical News.

THE seventh annual lecture conference of the Industrial Welfare Society has opened at Balliol College, Oxford, and will continue until next Wednesday. A lecture on dental service in industry is being given to-day (Saturday) by Mr. H. A. Mahony, secretary of the Public Dental Service Association of Great Britain, and Dr. Innes H. Pearse will speak on the future of preventive medicine in industry on Tuesday afternoon.

AN intensive course in operative surgery at the Central London Throat, Nose and Ear Hospital, Gray's Inn Road, W.C.1, will commence on October 4th, preceded by a preliminary course of six lectures on methods of examination and diagnosis, which starts on September 15th. The syllabus may be obtained from the dean at the hospital.

A SPECIAL two weeks' course in orthopaedics will be given at the Royal National Orthopaedic Hospital from September 20th to October 2nd. The fee is two guineas. The course is open to all post-graduates, and further particulars may be obtained by applying either to the Secretary, Royal National Orthopaedic Hospital, 234, Great Portland Street, London, W.1, or to the Secretary, Fellowship of Medicine, 1, Wimpole Street, W.1.

THE Minister of Health has issued a circular letter (735) to the effect that the Civil Service bonus will be based from September 1st, 1926, on an average cost of living figure of 70. The bonus payable for the six months commencing on this date to officers whose annual salaries do not exceed £500 will therefore be one-eighth less than that paid during the six months commencing on March 1st. Officers whose remuneration from local authorities is subject to the sanction of the Minister of Health are similarly affected.

THE twelfth annual report (for the year 1925) of the International Health Board of the Rockefeller Foundation by the general director, Dr. Frederick F. Russell, gives in greater detail and with admirable illustrations the data summarized in the review of the president of the Foundation, who is also chairman of the International Health Board. In hookworm disease the use of carbon tetrachloride, which is more effective than other means, is, like them, occasionally followed by poisoning, and most often when taken in association with alcohol or by children with *Ascaris lumbricoides*, and gives rise to necrosis of the liver; to diminish the risk it is administered in combination with oil of chenopodium, which is highly effective in removing ascarides. Further evidence has accumulated to confirm Dr. H. R. Carter's conclusion that in South America *Anopheles quadrimaculatus* is the important vector of the malarial parasite. As a result of the increase of malaria in Europe since the war a station was in 1925 established in Corsica to study its epidemiology and train malariologists for work in Europe.

THE Home Secretary gives notice that he has withdrawn from John Symington Stewart, M.B., Ch.B., of 252, Morrison Street, Edinburgh, the authorizations granted by the Regulations made under the Dangerous Drugs Act, 1920, to duly qualified medical practitioners to be in possession of and supply raw opium and the drugs to which Part III of the Act of 1920 applies, and has also directed that the exception in Regulation 4 of the Dangerous Drugs Regulations, 1921, which permits dangerous drugs to be supplied on a prescription given by a duly qualified medical practitioner, shall not apply in respect of prescriptions given by Dr. John Symington Stewart. Any person supplying Dr. Stewart with raw opium or any of the drugs to which Part III of the Dangerous Drugs Act, 1920, applies, and any person supplying the drugs on a prescription signed by Dr. Stewart, will be committing an offence against the Acts.

THE annual report of the National Institute for the Blind is a most excellent and interesting statement of the valuable work done by this organization. There is scarcely a single part of the whole range of activity of blind persons in which the institute does not take a leading and directing part. The activities of the institute include the printing of books for the blind, the production of newspapers, the organization of home visits to blind infants, the two colleges for the blind children at Worcester and Chorley, the training of blind workers in which the institute takes a large part in co-operation with local authorities. A new and useful feature of the report is a "Who's Who" of the executive council of the institute, which is compiled by similar charitable organizations, and is of great value by frankness of statement. The total income of the institute for the year 1925-26 was £312,411; the accounts for each branch of the institute's work are set out separately; in many cases they are pre-

sented in the form prescribed by the Ministry of Health or the Board of Education, and in all instances they are so clearly stated that the least knowledgeable in financial affairs cannot fail to understand their import. A new form of activity which has engaged the attention of the institute is assistance and advice in the provision of wireless sets for the blind. Broadcasting is one of the most valuable means of bringing the blind into close touch with the life of to-day. Braille newspapers cannot hope to give them all the information that is desirable. A beginning was made in a small way through the thought of some readers of newspapers, and the institute has taken the matter up with enthusiasm; it is aided by technical advisers. For a gift from the sighted to the blind there can be none better than a wireless set, or the putting of the blind person in the way of securing an efficient and simple set for himself.

COURSES of lectures and demonstrations at the Royal Sanitary Institute will commence on October 4th for sanitary inspectors, and on October 8th for meat and food inspectors. Further information may be obtained from the Secretary of the Institute, 90, Buckingham Palace Road, S.W.1.

ACCORDING to the Health Office of the Swiss Confederation the epidemic of small-pox in Switzerland, which has lasted for five years, is dying out. Only 329 cases were notified in 1925, as compared with 1,274 in 1924.

THE thirty-fourth Italian Congress of Surgery will be held at Padua from October 25th to 28th, when the following subjects will be discussed: (1) The surgery of the visceral sympathetic, introduced by Professor M. Donati of Padua. (2) The surgical treatment of pulmonary tuberculosis, introduced by Professor Leotta, representing the Italian Society of Surgery, and Professor F. Galdi, representing the Italian Society of Internal Medicine.

THE seventh congress of the German Society of Urology will be held at Vienna from September 30th to October 2nd, when the following subjects will be discussed: the pathology, pharmacology, and treatment of anuria; the pathology and treatment of malignant growths of the bladder. Further information can be obtained from the secretary, Dr. H. G. Pleschner, Alscsstrasse 20, Vienna IX.

THE centenary of Laennec's death was recently celebrated at Plouarnec, near Douarnenez, where he died. Addresses were delivered by Professors Chauffard and Marcel Labbé, and Dr. Laigriol-Lavastere.

## Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **THE EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1.**

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the **BRITISH MEDICAL JOURNAL** alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the **BRITISH MEDICAL JOURNAL** must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the **JOURNAL**, should be addressed to the Financial Secretary and Business Manager.

THE TELEPHONE NUMBERS of the British Medical Association and the **BRITISH MEDICAL JOURNAL** are **MUSEUM 9561, 9562, 9563, and 9564** (internal exchange, four lines).

THE TELEGRAPHIC ADDRESSES are: **EDITOR of the British Medical Journal, Astology Westcent, London.**

**FINANCIAL SECRETARY AND BUSINESS MANAGER** (Advertisements, etc.), **Articulate Westcent, London.**

**MEDICAL SECRETARY, Medicera Westcent, London.**

The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: **Bucillus, Dublin**; telephone: 4731 Dublin), and of the Scottish Office, 6, Drumsheugh Gardens, Edinburgh (telegrams: **Associate, Edinburgh**; telephone: 4361 Central).

## QUERIES AND ANSWERS.

### X-RAY TREATMENT OF RINGWORM.

"T. E. R." asks for advice on the use of filters in x-ray treatment of ringworm of the scalp. Is any advantage to be gained, he asks, from the routine use of aluminium filters of, say, 1 or 2 mm. thickness, either as regards increased safety or more uniform results in epilation? If so, how is the exposure calculated (taking 4/5 tint B Sabourand as a safe unfiltered dose), and is the pastille exposed to filtered or unfiltered rays?

## ELECTRIC CURRENT.

DR. J. S. TOWNLEY (Crickhowell) asks how many Léclanche cells would be needed to pass a current of 5 to 20 milliamperes through a 12 st. man from the mastoids to the hands, and what such a battery with proper resistance would cost approximately?

Approximately thirty cells. A resistance would not be wanted, but a collector switch would be required, so as to be able to switch in (say) at twenty cells and afterwards to thirty. The cells cost 2s. 6d. each. A collector switch on the board would have to be specially made, and 30s. should be allowed for that. A better arrangement would be a self-contained battery of dry cells—generally forty cells—in a box, with a collector switch all mounted up together. This gives a slower and better regulation, and is a recognized piece of apparatus in electro-medical catalogues. The cost is about £9; this is higher than the other arrangement, but it has the advantage of being a single unit.

## CHRONIC ULCERS OF MUCOUS MEMBRANES.

DR. C. E. PRATT (Bexley Heath) writes, in answer to "A. F.'s" question (August 28th, p. 407) as to the treatment of chronic ulcers of mucous membranes, to recommend a course of colossal manganese and small doses of thyroid. Of the former he advises  $\text{mxx}$  three times a day in water, gradually increasing to 1 drachm; of the thyroid a tablet of  $\frac{1}{2}$  or 1 grain.

## ASTHMA AND BRONCHITIS.

"GENERAL PRACTITIONER" writes in reply to "P.'s" query id bronchitis: I prefer to relieve the mixture recommended, I believe, Ammon. chlor. gr. x, Potass. bicarb. gr. xv, Liq. picis aromat. (Bell) 5ss, Ext. glycyrrh. liq.  $\text{mxx}$ , Tinct. cardam. co. 5ss, Aq. ad 5ss; in water every four hours. The asthmatic element, provided no immediate cause can be found, is relieved by hypodermic injections of pituitary extract and adrenaline. The administration of 1 c.cm. of pituitary extract and 0.5 c.cm. of adrenaline 1 in 1,000 gives in nearly all acute attacks almost instant relief, and I find that a course of six injections at intervals of five days is followed by a period of, usually, several months free from attacks, and with breathing comfortable. In the case of a woman aged 56, who had suffered fairly continuously for several years, there has been no return of asthma for five years, save once, three years ago, when the attack was immediately stopped after one injection. The combination of pituitary extract and adrenaline is that usually supplied in ampoules by manufacturing chemists.

## INCOME TAX.

"J. E. F." says: I buy a practice for £700 and sell it in six months for £500; the profits for that time are £200; previously they averaged £500 a year, but were decreasing. On what sum am I liable for tax for that six months?

On £200—but it will be necessary to make special application for the reduction of the assessment for the six months to that figure, on the ground that the profits fell off subsequent to the succession from some specific cause. The £200 lost on purchase and sale of the practice represents a loss of capital and not an expense of working the practice.

## LETTERS, NOTES, ETC.

## ACUTE PULMONARY OEDEMA.

DR. F. B. JULIAN (Liverpool) writes: In the BRITISH MEDICAL JOURNAL of June 19th (p. 1033) reference is made to contributions by myself and others, on the subject of acute pulmonary oedema, in the JOURNAL of April 17th. As I have also received inquiries by letter, perhaps you will allow me space in which to make reply. One of your correspondents considers my action in administering antimony tartrate as open to serious criticism. Had I given the antimony in the usual form and dosage I would agree. The phrase "guided by the principle of similars," however, should have made it clear that the antimony was not administered in the usual dosage, for this principle—otherwise known as the homeopathic principle, and utilized successfully but unconsciously by thousands of medical men who would refuse to admit a close correspondence between the symptomatology of the drug used and the consequently demands attention of the dose. The dose administered by me in the case recorded was attenuated to a degree which rendered it infinitesimal. The result was, however, as noted, both effective and dramatic.

## VENEREAL DISEASE PROPYLAXIS.

DR. M. W. BROWDY (London, W.) writes: As reported in the BRITISH MEDICAL JOURNAL (August 7th), the Society for the Prevention of Venereal Disease at its annual meeting passed a resolution to urge the Government to amend the Venereal Diseases Act, 1917, so as to permit the sale by chemists of approved disinfectants. Without entering into the problem of prophylaxis, I would draw attention to the evidence now accumulating of primary syphilis retarded by prophylactic treatment and the consequent danger of neuro-syphilis. This alone should make one pause before recommending such a measure. At the same meeting attention was drawn to the remarkable fall

in the incidence of venereal disease during the last four years, attributable to the prevention, diagnosis, treatment, and anti-venereal disease propaganda. Might I ask if this is so? Does it not merely indicate a gradual clearing of those infected during the war period? The only comparison lies between new infections, pre-war and present day; and if this comparison were made it would probably be found that the removal of the only deterrents to promiscuous sexual intercourse—namely, fear and cost of treatment—has produced very little change in the incidence.

## MINER'S NYSTAGMUS.

DR. T. L. ASHFORTH (Doncaster) writes: After twenty-five years' experience in Scotland (Lanarkshire), Durham, and South Yorkshire coalfields I agree with Mr. A. S. Percival (July 31st, p. 224) that the light conditions have nothing to do with miner's nystagmus, nor have errors of refraction. I have read the Commission's Report, and I am afraid many practitioners with vast colliery experience will only smile at it. If one wants a reliable statement of affairs, bring the matter up at a meeting of the British Medical Association or a special conference or conferences at certain centres and invite everybody interested to attend.

## TUBERCULOSIS AND THE STATE.

DR. A. J. BROCK (North Queensferry, N.B.) writes: I have read and enjoyed your summary in the BRITISH MEDICAL JOURNAL of August 21st (p. 349). The subject is, to say the least of it, complex. Might I suggest that, in order to distinguish the wood from the trees, a useful beginning might be made if we all definitely realized the following principle: that there are two chief kinds of tuberculosis—one pathological and the other physiological. Some expense might then be saved if we stopped attempting to cure cases belonging to the latter category.

## THE REVISION OF THE "BRITISH PHARMACOPOEIA."

DR. GEORGE W. CHEATER (Woodford Green, N.22) writes to suggest that on the proposed new edition of the British Pharmacopoeia, which has had experience as a qualified member of the B.P. professions; not only to be given, but also could points of view, for he is a B.P.'s the medical men have not always seen eye to eye with the pharmacists and vice versa. For instance, there are several preparations which are prescribed with extreme rarity by the medical profession and, from the pharmaceutical aspect, are anything but elegant, such as mist. galuaci and mist. ferri co. Again the number of ingredients of confectione senae might be "pruned" down by half without any detriment to its medicinal value. This point, he is sure, will be endorsed by anyone who has had to make it by hand in his apprenticeship days.

## GOLDFISH AND MOSQUITOS.

A CORRESPONDENT, jealous of the space of the JOURNAL, asks us why room was found for a short review of a book on how to keep goldfish, published on August 28th (p. 390). The answer is that goldfish eat mosquito larvae. This well known fact may be illustrated by a true story. Not long ago a teacher about to give a lecture on malaria wanted to show his class some larvae, but they were not to be obtained from the animal dealers. In despair he offered a penny apiece. A colleague who, ever since he had made himself a small ornamental pond in his garden, had been plagued by mosquitos, thought he saw a way of turning a few honest pennies. When he got to the pond side he could find no larvae, nor any mosquitos. The explanation, which satisfied him, was that not long before he had put into the pond a few goldfish, and they had swept it clear of larvae.

## FORD CARS.

WITH The Original Book of the Ford no driver of that estimable vehicle need fear any trouble. Mr. R. T. Nicholson's book is now in its tenth edition, so that students of the work must be numerous. Every detail of the car, and every possible disease or disorder, is described. Our only fear is that the owner who follows out all the directions given in the book may find that he has little time left for any other occupation than nursing his Ford.

## ERRATUM.

WE regret an error in our issue of August 28th (p. 376). The name of the President of the Section of Public Health should have been given as Dr. Philip Boobyer, instead of Dr. William J. Howarth, who was prevented by illness from being present at the Nottingham meeting.

## VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 40, 41, 44, and 45 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 42 and 43. A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 149.

SEPT. 18, 1926]

## SECTION OF PATHOLOGY AND BACTERIOLOGY.

### British Medical Association. PROCEEDINGS OF SECTIONS AT THE ANNUAL MEETING, NOTTINGHAM, 1926. SECTION OF PATHOLOGY AND BACTERIOLOGY.

Professor J. SHOLTO C. DOUGLAS, M.D., President.

#### PRESIDENT'S OPENING REMARKS.

THE President, in opening the proceedings of the Section, paid a warm tribute to the memory of Sir William Leishman, who, but for his much lamented death, would have presided over the meetings of the Section. Sir William Leishman, said Professor Douglas, was one of the small band who worked out the preventive inoculation against the enteric disorders, with the result obtained in the recent war. The reduction in the case incidence and in the case mortality resulting from these labours was nothing short of miraculous. Leishman's stain had stood the test of time, and was now in such universal use as to have become a standard method in the clinical examination of the blood. Students of tropical medicine would long honour him for his discoveries in connexion with kala-azar, and here, too, his name will be handed on to posterity in the word "leishmania." He had devoted his life to the Royal Army Medical Service, and it was while serving it that he carried on his wonderful researches and stimulated others to a realization of the value of sound pathology. As professor of pathology in the Army Medical Department, and subsequently director-general, Sir William Leishman had done a great work and endeared himself to those who came into contact with him. His death had been an incalculable loss to the Pathological Section of the British Medical Association. They owed him much for the organization of this meeting, which he had left practically completed.

#### DISCUSSION ON THE RELATION OF STREPTOCOCCI TO SCARLET FEVER AND ITS COMPLICATIONS.

##### OPENING PAPERS.

I.—R. A. O'BRIEN, C.B.E., M.D. MELB.,  
Wellsome Physiological Research Laboratories, Beckenham, Kent.

THE title of our discussion assumes that a relationship exists between streptococci and scarlet fever. It may be of service to sum up the grounds for the acceptance of this assumption and for our personal belief that streptococci are the cause of scarlet fever. Haemolytic streptococci have been found practically always present in true scarlet fever. Clinical scarlet fever has been produced (according to the statements of the Drs. Dick) by the swabbing of cultures of these streptococci on to the tonsils of susceptible people; a culture filtrate or "toxin" prepared from the streptococci gives reactions which are specifically related to scarlet fever, for practically all patients, in the earliest stage of the disease, give a positive response to the intracutaneous injection of the toxin, and during convalescence, when their immunity is developed, the serum of immunized patients give a negative response to their toxins, when immunized with these streptococci or their toxins. Injected intracutaneously, produces the serum of infectious of a scarlet fever rash; finally, the serum of immunized animals has what, in the opinion of medical men with long training in the observation and treatment of infectious fevers, amounts to a specific curative action. This "conviction of faith" will cause a certain repetition in the logical consideration of our subject, but it has appeared advisable to define at the outset what is believed to be the ground already won.

When the subject of our discussion was chosen, some months ago, it was fervently hoped that before this meeting a test applicable in the laboratory for the measurement of

scarlet fever toxin and antitoxin would have been discovered, and that with such a test we should have been able to clear up many uncertainties. That hope proved vain, for no satisfactory test has yet been found. In consequence we shall be obliged to some extent rather to formulate questions than to add much to our common stock of knowledge.

We are to inquire, What is the relation of the *Streptococcus haemolyticus* to scarlet fever and its complications? There seems little doubt that haemolytic streptococci are closely related to scarlet fever, and we are justified, for the purpose of discussion, in postulating a "*Streptococcus scarlatinae*" (or possibly a group of streptococci) which causes infectious scarlet fever. But as soon as we seek to define this *S. scarlatinae* our difficulties begin. If we isolate from the throat of a patient suffering from scarlet fever a streptococcus which we think may be the characteristic organism, we must determine that it is haemolytic, and that on the ordinary media it grows like the haemolytic streptococci obtained from any other pathological conditions; it has, unfortunately, no characteristic growth sufficiently distinctive to help us materially in identification. Its fermentation reactions must agree with those of *Streptococcus pyogenes*; lactose, salicin, and saccharose must be fermented, but not raffinose or inulin; mannite is fermented by some strains and not by others, yet in both cases we must accept these strains as true *Streptococcus scarlatinae*. (In passing we may note that this character appears to be not very deeply implanted, for a strain of the mannite-fermenting variety, which Dr. Dick kindly sent us, has in our laboratory, in the course of some months, apparently lost its power to ferment mannite.)

The organism, when grown in ordinary peptone or tryptic digest broth, must produce in the filtrate a "toxin" having the same property as that described by G. F. and G. H. Dick. It must, in a reasonably high dilution, give a positive "Dick" reaction in almost all cases of scarlet fever tested during the first two or three days of the disease; it must, when injected into positive Dick reactors in a quantity containing about 1,000 times the minimal skin reacting dose, produce in the majority of instances a "miniature non-infectious scarlet fever" or the "scarlatinoid syndrome"—that is, sore throat, fever, vomiting, and characteristic rash; it must be neutralized by the specific antiserum, so that when a mixture of toxin and antitoxin is injected intradermally into a positive reactor to the Dick test, no reaction is produced. Before our scientific scepticism is satisfied we may ask more—that is, that our living culture will, when applied to the throat of a positive Dick reactor, produce unmistakable scarlet fever. It is probable that only three strains in existence have had their authenticity tested thus far—the mannite-fermenting and also the non-fermenting strains of the Dicks, and one strain in Park's laboratory, which was accidentally sucked into the mouth of a worker and apparently caused typical scarlet fever.

We may inhumanly still press our demands and say that we are not yet satisfied, for natural scarlet fever is infectious, and we have yet to prove that the disease we have produced will infect susceptible contacts as the natural disease does. This test has not been carried out, nor is it probable that our common humanity will ever allow it. It is only the interesting history of swine fever that makes us even contemplate such a demand. Until Dorsett's classic investigation it was everywhere accepted that the *B. suis* bacterium was the cause of swine fever, for the disease this bacillus produced was not infectious, and it was only when he obtained his "filterable virus" from bacilli that he was able to produce a disease clinically resembling natural swine fever and also resembling it in its intense infectiousness. The *B. suis* bacterium is apparently a "secondary invader" which produces the ulcers, and is so commonly present in pigs in most countries where true swine fever occurs that in the opinion of those charged with the control of animal diseases it is safe to found a diagnosis of swine fever, justifying administrative measures, on the finding of the ulcers really caused by *B. suis*.

[3428]

With regard to septic complications, there seems little doubt that the majority of the organisms causing otitis, septic adenitis, etc., belong to the *Streptococcus scarlatinae* group, for a number of workers (Stevens and Dochez, 1926; J. Smith, 1926; etc.) have isolated strains from such complications which agreed with the Dochez-Dick strains in every test which was applied.

There remain for discussion at least three important questions:

(a) Given a haemolytic streptococcus of unknown origin, can we decide quickly and certainly whether it is a *Streptococcus scarlatinae* or not?

(b) Are there different types of scarlet fever caused by different strains of the streptococcus, or is there but one clinical scarlet fever caused by serologically differentiable streptococci?

(c) Does the *Streptococcus scarlatinae* attack only as a toxic organism, or has it another mode of attack which we may call the septic or pyogenic method?

Our best hope of getting answers to questions (a) and (b) lies at present in the agglutination and intracutaneous tests.

**Agglutination.**—There seems little doubt, from the investigations of the past few years in which both American and English workers have played an important part, that the agglutination and agglutinin-absorption methods are of service. If one handed to any of these workers two groups of some twelve strains of haemolytic streptococci, one group taken from the throats of scarlet fever patients, the other from patients suffering from erysipelas, puerperal fever, or septicaemia, etc., it is probable that in every such experiment the scarlet fever group would be identified with certainty. But if one wishes to identify individual cultures difficulty arises. Our own limited experience suggests that a small number of individual strains fail to give satisfactory results, and it is interesting to note in the American literature the occasional reservations of the more critical workers that a certain small proportion of strains will not form stable suspensions or do not fall clearly into the scarlet fever agglutination group or subgroups. Stevens and Dochez (1926) stated their position thus:

"Erysipelas strains form a closely related group of haemolytic streptococci. Scarlatina strains form an equally compact group. The two groups are related antigenically, but less closely related than the strains within the groups. These groups are related to pathogenic strains, but less closely than they are related to each other."

Had these authors added that there were apparently subgroups, as indicated by agglutination and absorption reactions, inside the scarlet fever group, etc.,<sup>1</sup> their position would have corresponded almost completely to that of most American workers and of Gordon, Smith, Eagles, and F. Griffith in England.

The answer to our first question is that, unfortunately, we cannot quickly and certainly identify a given haemolytic streptococcus as *Streptococcus scarlatinae*, for though the group is fairly clearly defined serologically, occasional scarlet fever strains fail to agglutinate with the specific scarlet fever serum, and some strains derived from other diseases agglutinate and absorb with the specific serum. The difficulty in dealing with suspected "carriers" is unfortunately obvious.

If we attempt to answer question (b) by the agglutination method we cannot give a clear reply. From various published reports (notably that of J. Smith)<sup>2</sup> it seems fairly certain that inside the scarlet fever group of streptococci it is possible by agglutination to define more or less closely several subgroups. The biological significance of these subgroups we cannot at present determine. So far as I know, no worker has suggested that these different subgroups are associated with different varieties of scarlet fever. Our own results in diphtheria, where we can take a group of true virulent *C. diphtheriae* excreting a toxin neutralizable by one specific antitoxin, and proceed by agglutination and absorption methods to differentiate a large number of subgroups, make us disinclined to believe that this serological subgrouping has any pathological significance.

**Toxicogenic Power.**—There remains another method of attempting to answer questions (a) and (b). The specificity of the intradermic toxin reaction is high, but it is probably

not as absolute as it certainly appears to be in connexion with *C. diphtheriae*. If a haemolytic streptococcus which grows normally and is specifically agglutinated by anti-streptococcus agglutinating serum produces a toxin which is neutralized only by scarlet fever antitoxin, the evidence that the organism is a *Streptococcus scarlatinae* becomes almost convincing. Yet in the light of the available evidence it cannot be said that the absence of this toxicogenic power is sufficient *absolutely* to exclude a given organism from the scarlet fever group, or that its presence warrants a dogmatic assertion that the organism is undoubtedly the *Streptococcus scarlatinae*.

The idea that there may be varieties in the toxins produced by the group of scarlet fever organisms has suggested itself, and Park<sup>3</sup> has, from his observations on specific neutralization with scarlet fever serum, recently put forward the conception that there may be groups of streptococci which produce toxins not identical but having an antigenic overlap.

**Schultz-Charlton. Blanching.**—This test may carry us a little further. If an antitoxin made by injecting animals with the toxin of a given streptococcus blanches the rash of scarlet fever and not of measles, rubella, enema rashes, etc., there is strong justification for considering the organism as the specific *Streptococcus scarlatinae*. Yet even here we must make a slight reservation, for, though we know that the great majority, some 80 to 95 per cent., of scarlet fever patients, if tested within seventy hours of the appearance of the rash, will show the specific blanching, we cannot be certain that we can produce the phenomenon on 100 per cent. of patients tested. Since scarlet fever antitoxin produced in the horse, or the serum of a patient convalescent after scarlet fever, will "blanch" a very high percentage of scarlet fever rashes, we are justified in considering all strains of *Streptococcus scarlatinae* as toxigenically identical. It is true that few clinicians obtain 100 per cent. of positive blanching results when testing scarlet fever patients, but so far as one can judge from the very meagre observations available, the serum of these "non-blanching" patients, taken during convalescence, will in its turn blanch ordinary scarlet fever rashes, which also blanch with the antitoxin serum produced in the horse. There is here no clear evidence that there are two types of scarlet fever.

Our answer to the second question, then, is that there is probably only one type of clinical scarlet fever, which may be caused by a group of haemolytic streptococci containing subgroups that are differentiable by agglutination methods, but not at present clearly separable by intracutaneous injection of toxin or the Schultz-Charlton method of test. "Puerperal scarlet fever" and "surgical and burns scarlet fever" are puzzling syndromes, and their relation to ordinary infectious scarlet fever is not at present clear. Many authorities consider these attacks as true infectious scarlet fever occurring in patients whose illness may possibly have increased their liability to scarlet fever; others think that such patients develop "scarlet fever"—that is, fever with scarlatiniform rash but with little or no inflammation of the throat—caused by streptococci derived from the vagina or wound, which may not be identical with the ordinary *Streptococcus scarlatinae*; further, that such attacks are not infectious, probably because the cocci are not liable to be spread as droplets in coughing and talking as they are in an ordinary attack of scarlet fever with sore throat. It should be easy, by a careful study of such cases by means of the Dick and Schultz-Charlton reactions, and of the cocci isolated therefrom, to establish clearly what is the relation between these curious attacks and true scarlet fever.

In attempting to answer our third question the available data at present are insufficient to give much help. The large amount of evidence available has convinced practically all observers that scarlet fever antitoxin is a specific curative serum, and that, given early in the disease, its beneficial action approaches that of the specific antitoxin used in the treatment of diphtheria.

In addition, considerable evidence is also available suggesting that the giving of antitoxin early in the disease decreases the liability to complications. Some clinicians state that scarlet fever antitoxin will benefit late septic cases also; most physicians have had no such good

SEPT. 18, 1926]

results. If "late septic cases" gave invariably or usually a "Dick-positive" response this would be fairly clear proof that they possessed little or no antitoxin, and one could believe that the antitoxic serum might be useful. Unfortunately, no long series of Dick tests on late septic cases have been published, but apparently these patients more often than not show a negative response to the test. We would not, therefore, expect antitoxic serum to benefit these patients. If further experience were to prove that the giving of purely antitoxic serum to "septic" cases is beneficial we should almost be compelled to believe that the "toxic" mode of attack of the streptococcus is by far the most important and almost the only one—that is, that the toxin causes local damage in the ear or in the tissues, and that in this damaged area the streptococci, which must be circulating in the patient's blood at some stage of his illness, can settle down and produce further damage.

The laboratory evidence is at present against the extreme view that the toxic attack is all-important and the attack by the living streptococcus but of secondary import. The rabbit is almost completely resistant to the toxin of the *Streptococcus scarlatinae*, whether given intracutaneously, subcutaneously, or intravenously, whereas the living culture injected intravenously kills, and, given intracutaneously, causes a large lesion often followed by septicaemia and death.

#### Summary.

Haemolytic streptococci cause infectious scarlet fever. These streptococci tend to form a group which can be differentiated by agglutination methods from the haemolytic streptococci of erysipelas, septicaemia, puerperal fever, etc. There is some agglutination relationship between the more or less sharply defined scarlet fever group of haemolytic streptococci and the groups associated with other diseases. The streptococci causing the "septic" complications of scarlet fever probably usually belong to the group of scarlet fever haemolytic streptococci.

II.—C. C. OKELL, M.C., M.B., M.R.C.P., D.P.H.,  
Wellcome Physiological Research Laboratories, Beckenham, Kent.

WITH regard to the validity of the streptococcal theory of scarlet fever there seems little to add to the general statement of the opener of this discussion. It cannot, of course, be maintained that the streptococcus is the cause of scarlet fever with the same certainty that the Klebs-Loeffler bacillus is the cause of diphtheria. At the same time the work of the Dicks and Dochez has shown how profitable a working hypothesis the streptococcal theory of scarlet fever has proved. It would be unwise, however, to overlook the possibility of other agents being involved in the etiology of the disease. All who have worked in this field have met with facts which appear to be discordant with the simple statement of the theory. That this is admitted, but it affords no reason for attacking any new problem is the usual state of affairs in attacking the difficulties and must also be confessed that in this subject the difficulties and discrepancies become more numerous with the progress of observation and experiment.

The solidly established facts are: (1) The Dick test indicates—though by no means with precision—the state of susceptibility or non-susceptibility to the disease. (2) Streptococcal "antitoxin" has a curative value in suitable cases of the disease. There seems little doubt that both the toxigenic and the progenic activities of the scarlet fever coccus are responsible for most of the clinical manifestations of the disease, and that the injection of sterile toxin alone can produce a syndrome bearing the closest resemblance to scarlet fever.

With regard to most other aspects of the problem there seems much to be said on both sides. It has been frequently pointed out that one great obstacle to the advance of knowledge on this subject is due to the difficulties in titrating both scarlet fever toxin and antitoxin. To begin with, the only animal which has been conclusively shown to be susceptible to the toxin is the

human being, and such progress as has been made is entirely due to experiments on human volunteers. The activity of toxin is estimated from its activity on susceptible persons, but it must be remembered that probably comparatively few people, especially in the older age groups, can be taken as being virgin soil so far as scarlet fever infection is concerned, and still fewer so far as streptococcal infections in general are concerned. This may or may not be the explanation of the difficulty met with in trying to compare the activity of two toxins. One can imagine the uncertainty that would have arisen in connexion with the similar problem in diphtheria had only experimental animals been men or horses, who have so frequently acquired some degree of immunity to that infection. As it is, the comparison can only be made after a large series of observations and with great caution.

The difficulties of finding the neutralizing power of an antitoxin in terms of a known toxin dose are still greater. One of the difficulties is that reactions due to the serum may be misleading, but even apart from this it has proved very difficult to evaluate either serum or toxin in terms of the only phenomenon which is at present available for the purpose—namely, the delicate skin reaction due to the toxin. The toxin reaction, indeed, appears to be almost entirely a vasomotor effect, and can be easily disturbed by non-specific factors. It tends, moreover, to be an all or nothing phenomenon. It may happen that injections containing very different amounts of toxin produce almost indistinguishable reactions. In the case of diphtheria toxin the size of the reactions bears a definite relation to the amount of toxin used.

Most of those who have experience in titrating streptococcal antitoxin in terms of skin doses of toxin admit that very wide discrepancies may occur even when the greatest pains have been taken to ensure standardized conditions of test. In some cases the neutralizing value of a sample of serum, as determined by different observers in terms of skin doses of toxin, has varied as much as tenfold. Under such conditions it is obviously premature to lay down standards of either toxin or antitoxin. Most of the competent authorities in America seem to be in agreement that such standards as are chosen should be of a purely provisional character.

If accurate standardization is aimed at it is important that the fundamental standard should be that of a serum rather than a toxin. Drs. McCoy and Dyer of the Hygienic Laboratory in Washington have prepared a serum which they propose to issue as a provisional standard, and there seems no reason why this should not be accepted in this country also. It is a serum of apparently high antitoxin content, and will serve as a constant for comparison until more definite standards can be laid down. The method at present customary in America of giving the titre of antitoxin in terms of units is liable to be misleading, and in this country we have not as yet seen any sound reason for adopting it. The present position in regard to the standardization of scarlet fever serum may be summarized as follows: The distinction of good from bad serum depends ultimately on its therapeutic effect. By means of toxin neutralization tests, blanching tests, or the passive immunity method, the therapeutic value of the serum can be predicted, but at the moment anything like close quantitative comparison of serums is impossible. On the evidence available it is not even clear which of the methods customarily used in evaluation is the best. The important thing for the time being is that what titration experiments efficiency be issued, and that the question of test which do indicate as the effective dosage should be stated.

Before leaving the question of toxin and its titration reference should be made to the methods of test which do not involve the use of human subjects. The *in vitro* methods on the lines of the Ramon test gave no results in our hands. Like Dyer we found that flocculation occurred in mixtures of scarlet fever toxin and antitoxin, but we could establish no numerical relationship between the two. This is confirmed by Dyer's latest and as yet unpublished work. No animal we have tried has reacted at all promisingly to the toxin except the goat. This animal has been used by Kirkbride and Wheeler for the titration of toxin and antitoxin. We have found goats

which reacted to 0.2 c.cm. of very dilute (1 in 4,000) toxin, but here again the numerical difficulty occurred. As much as 80 times the minimum reacting dose produced a reaction of very much the same size as the minimum reacting dose. One goat also, which gave a good reaction intradermally with 0.2 c.cm. in 1 in 1,000 dilution, failed to show the least abnormality when 5 c.cm. of pure toxin was given subcutaneously. If the skin reaction in goats is therefore a true toxin effect it is strange that 25,000 skin doses should produce no effect, general or local, when given subcutaneously. It would be unwise to say that the goat cannot function as a test animal, but until such discrepancies as we have mentioned can be explained away it would be as well to be cautious.

It must not be forgotten that it is one of the most characteristic properties of a true toxin that the toxic effect produced is proportional to the amount of toxin given. Dick toxin, as regards its effect on human beings, falls into line with other toxins. As far as the work of Parish and myself has been concerned this has not been the case with goats or other animals, and we are disposed to look upon such reactions as are produced in these animals by filtrates as due to some form of allergy rather than to a true toxin effect.

Another point to which I wish to refer is of both clinical and immunological importance. The streptococcus plays a dual role in scarlet fever: (1) it produces a toxin, and (2) it may invade tissues like any other pyogenic organism. Uncomplicated scarlet fever appears to be almost purely a toxæmia, which is rapidly combated by the production of streptococcal antitoxin; but the streptococcus can, and often does, take a further role as an invasive organism, producing effects similar to those produced by any other pyogenic streptococcus. The pyogenic function of the streptococcus appears to be more or less separate from the toxæmia function from the immunological and even from the clinical point of view.

The most important fact bearing on this is that the patient who has a pyogenic complication of scarlet fever is "immune" to the toxin—that is, he almost always has a negative Dick reaction. Once pyogenic complications are established antitoxin serum has no effect on them. This dual nature of the streptococcus is paralleled by animal experiments. Mice and rabbits are not susceptible to the streptococcal toxin, but they may be killed with a septicæmia by the scarlet fever coccus. Rabbits may also be given a typical pyogenic infection of the skin with the scarlet fever streptococcus. It is not clear that any amount of scarlet fever antitoxin *per se* can be depended upon to protect against such infections. H. J. Parish, working with me on this point, has been unable to show that serums prepared either against toxin or bacterial bodies are able consistently to prevent the septicæmia of mice or the pyogenic skin reactions in rabbits. On the other hand, rabbits may be killed with 5 c.cm. of a young broth culture of the scarlet fever streptococcus, given intravenously. Scarlet fever antitoxin which was prepared entirely by immunization with sterile filtrates (toxin) when given five hours beforehand will prevent the death of the rabbit. Under certain conditions of experiment this effect is quite constant. It is not clear to us if this preventive property of the "antitoxin" is purely an antitoxic effect, but if it proves to be such it gives us hope that an animal test of an antitoxic activity might be evolved on the basis of Parish's experiments. If, on the other hand, the effect is due to the accidental presence of an antibody other than antitoxin it still seems worthy of close investigation, since a serum rich in such antibody might be useful in treating human patients in the pyogenic stages of the disease.

Though scarlet fever antitoxin does not deal with all the pathogenic activities of the streptococcus it is very important as a therapeutic agent. Experience has been uniformly in favour of the view that if it is given sufficiently early it tends to prevent the septic complications of the disease. The aggressive action of the toxin seems to be an important factor in the invasive power of the streptococcus. Antitoxin appears, therefore, to be an invaluable therapeutic agent in the toxic phase of scarlet fever, while it is quite ineffective in the purely pyogenic phase of the

disease. Indeed, in the pyogenic phase there is generally in the patient's serum more than enough antitoxin to do all that antitoxin can do.

With regard to the value of agglutination as a means of identifying scarlet fever streptococci I might refer to the results obtained by Miss G. I. Steed and myself. We examined thirty-four strains of hæmolytic streptococci from cases of scarlet fever by the technique described by Mervyn Gordon in his work on the subject. Twenty-seven strains absorbed the agglutinin from a serum made by injecting a rabbit with the killed Dochez streptococcus. The titre of the serum was 1 in 800. No detectable agglutinin was left when 1 in 100 was tested after absorption. Two strains completely failed to absorb agglutinin from this serum, but absorbed it from serum prepared from S. F. 18, a toxigenic strain isolated by ourselves. The two Dick strains, and also one from Dr. Anna Williams, only absorbed Dochez serum to 3/4 titre; S.F. 18 serum was completely absorbed by these three strains. Eleven strains of hæmolytic streptococci from sources other than scarlet fever—for example, puerperal fever, pyorrhoea, etc.—were also tested for absorption; the great majority of these did not absorb the agglutinin, but five strains which seemed to have no connexion with scarlet fever did absorb it. These were respectively a strain isolated from strangles in a horse, one from a case of pyorrhoea alveolaris, and two from cases of pyogenic infection. It was thus possible arbitrarily to separate by absorption the bulk of scarlet fever strains from non-scarlet fever strains, but not with sufficient certainty to allow the diagnosis of an individual strain. These results confirm the work of Stevens and Dochez, and other recent investigators. At the best positive agglutination or absorption results are but presumptive evidence that a given streptococcus is a scarlet fever organism.

### III.—KONRAD E. BIRKHAUG, M.D.,

New York.

From a bacteriological study of more than 500 cases of scarlet fever we have been able to isolate *Streptococcus scarlatinae* from the tonsillar crypts during the first three days of the disease in 97 per cent. of cases. Type specificity of these organisms was determined both by agglutination and absorption and by the toxigenic power and the specific neutralization of the toxin by *S. scarlatinae* antitoxin. The average duration of *S. scarlatinae* in the tonsillar crypts of clinical cases of scarlet fever was ten days, and after the disappearance of this organism an invasion of non-specific hæmolytic streptococci dominated. These were faintly toxigenic in nature and their toxic products non-neutralizable by the scarlatina antitoxin. It is curious to note that the disappearance from the throat of the *S. scarlatinae* is coincident with the appearance in the patient's blood serum of an adequate amount of antitoxin, which, when injected intradermally in the rash of an acute case of scarlet fever, will produce the Schultz-Charlton blanching phenomenon. The longest persistence of a true agglutinable and toxigenic *S. scarlatinae* in the tonsillar crypts of a scarlet fever patient was 246 days after the initial onset of the disease. Without being able legally to quarantine this patient, she was left at large. From the patient's family three members were returned to the hospital with clinical scarlet fever during the first two months after her return home, and the patient's father developed acute pharyngitis five months later. The culture of hæmolytic streptococcus isolated from the throat of the father revealed a true *S. scarlatinae*, but the "carrier" gave a negative Dick reaction to the toxin produced by his own organism. Williams and Stevens have already called attention to the wide distribution of *S. scarlatinae* in osteomyelitis, endocarditis, acute, subacute, and chronic tonsillar infections, without the clinical symptoms of true scarlet fever. The seriousness of the scarlatinal "carrier" problem in close as well as disseminated epidemics of scarlatina must some day demand the same attention we have paid to the diphtheria "carrier" problem. Dr. O'Brien has already so commendably pointed out the difficulty which confronts

us when we are called upon immediately to determine a *S. scarlatinae*. At the best it takes an expert bacteriologist about three days to make such a determination under favourable conditions. Inspired by the good results obtained by Ramon's flocculation method for determination of the antitoxic titre in diphtheria toxin on the water-bath, I laboured for several months in applying this the same in contact with diphtheria toxin on the water-bath, I laboured for several months in applying this highly specific reaction to determination of specific scarlatinal and erysipelas toxin-antitoxin neutralizations, but without any positive results. Until a quicker *in vitro* method is invented than agglutination and absorption, which in themselves are faulty and unreliable, in that they are produced by a number of non-specific strains, we may find the best method available that invented by Dick and Dick—namely, specific neutralization of *S. scarlatinae* toxin by scarlatinal antitoxin in the skin of susceptible individuals.

#### Varieties of *Streptococcus scarlatinae*.

Although several groups of *S. scarlatinae* are suggested by agglutination and absorption, yet, antigenically speaking, *S. scarlatinae* forms as compact and closely related a group of organisms as we shall shortly learn is the case with *S. erysipelas*. Toxigenically we are confronted with the problem of varieties of toxic products of true scarlatinal organisms. My experience has been the same as that of Wheeler and Kirkbride and Park, that one person may give a strongly positive Dick reaction to a toxin produced by one scarlatinal streptococcus and yet give no reaction with a five times stronger toxin of another individual susceptible to one toxin and not to that produced by another strain. Inasmuch as there is only one type of clinical scarlet fever and the specific curative effects of scarlatina antitoxin are unquestionably the same in every case treated early in the disease, is it not possible that the toxigenic power of *S. scarlatinae* presents a variable picture only *in vitro* after the organism has been artificially grown for some time, in, so to speak, unnatural surroundings? Our experience has been the same as that of Dr. O'Brien—that our original mannite-fermenting true scarlatinal strain lost its power to ferment mannite in the course of some months of artificial transplantations. May it not likewise lose its original toxigenic specificity? For practical purposes, then, a polyvalent toxin employed for the Dick test would give more uniform results than those already conflicting data obtained by the use of monovalent toxins.

#### Schultz-Charlton Phenomenon.

An interesting study has been in progress on the mechanism involved in the production of scarlatinal rash and its neutralization or blanching by means of specific scarlatina antitoxin. By studying microscopically the capillaries in the erythematous area during the height of the rash, we are able to count as many as forty capillary loops in one eye-field, using a magnification of 300 times. Normally only eight to ten loops come into view. When a deeply erythematous area of skin is infiltrated intradermally with 0.1 c.cm. of scarlatina antitoxin, we notice from hour to hour that the capillary loops diminish in diameter and that the flow of blood is retarded, and eventually, when the Schultz-Charlton blanching phenomenon is complete, we are able to discern only from eight to ten normally appearing capillary loops. When the scarlatinal rash is infiltrated with erysipelas antitoxin, diphtheria antitoxin, tetanus antitoxin, pneumococcus serum, or normal horse serum, the capillary picture remains undisturbed, or rather aggravated. When the scarlet fever patient's serum is taken during the first five days of the disease and injected intradermally in Dick-positive individuals, we obtain as a rule a strongly positive Dick reaction. If this serum is mixed with scarlatinal antitoxin and injected intradermally in Dick-positive individuals, no skin reaction is obtained. If, now, we take the patient's serum at about the twelfth day of the disease and inject it into the skin of Dick-positive reactors, we obtain no skin reaction; but if the same serum is injected intradermally into scarlet fever rash, we obtain in the course of ten to eighteen

hours the blanching phenomenon. There is here a strong justification for considering the antitoxin produced in the patients during the acute attack of scarlet fever identical with the antitoxin produced in laboratory animals by the injection of *S. scarlatinae*.

#### Specific Therapy.

The rapidly accumulating literature on the subject of specific scarlatinal antitoxin therapy makes it increasingly certain that we are dealing with a highly curative serum. My early observations with Dochez's serum in 1923-24 brought me to the conclusion that adequate doses of scarlatinal antitoxin administered during the first four days of the disease brought about a rapid recovery without septic complications. As Dr. O'Brien has already pointed out, I stated at that time that the antitoxin seemed without avail in the late septic cases, and during the past three years of continuous observation of specifically treated scarlet fever patients I have had no cause to change that early observation. The clinical picture of the late septic cases of scarlet fever resembles in some degree that of the late untreated case of diphtheria, in that it yields irregularly to massive doses of diphtheria antitoxin. It is possible that they cannot be neutralized by the administered antitoxin. In summary, then, we may say that the significance of *S. scarlatinae* in its relation to scarlatina is an established fact, which must remain as another milestone along the eternal road of medical progress—a milestone of which our profession should be doubly proud because the labours of two continents steeped in similar traditions and aspirations have made this monument to modern medicine possible.

#### GENERAL DISCUSSION.

The PRESIDENT asked whether complement fixation was of any avail in recognizing the streptococcus of scarlatina. It was difficult for the general pathologist to get first-hand experience of scarlet fever because cases were removed to special hospitals. These hospitals were so far away that it was quite impossible for the pathologist to pass from his laboratory to the bedside and to follow up his findings by the observation of cases. For this reason the knowledge of the pathology of infectious diseases, and therefore of their treatment, had been delayed. The best plan would be for the hospitals to follow the admirable example set by the Metropolitan Asylums Board and develop their own pathologists. At present the pathology was done by junior medical officers, untrained in this branch of work. This condition of things was most unsatisfactory.

Dr. W. J. TULLOCH (Dundee) said that two points of considerable importance arose out of the papers by Dr. O'Brien and Dr. Okell. The first was that apparently the *S. scarlatinae* was not, from the agglutinogenic point of view, a single definite entity, but was divisible into subgroups. Notwithstanding this it appeared from Dr. O'Brien's paper that all the immunologic varieties of *S. scarlatinae* produced the same toxin. There was here a close analogy with *B. tetani*, which, by the agglutination test, could be divided into several "types," but all those "types" produced the same neurotoxin. Therefore the toxic effect of any tetanus bacillus, no matter what its "type," could be neutralized by the antitoxin to any "type." The same was probably true of the diffusible toxins elaborated by *S. scarlatinae*. Therefore the toxin element in scarlet fever should be counteracted by an antitoxin prepared against any authentic strain of *S. scarlatinae*. There was, however, another aspect of the problem—namely, that the agglutinogenic types might be of importance in relation to infection, and, if this were so, typing by agglutination would assume considerable importance in connexion with prophylaxis. Recent work by Ten Broeck and Bauer suggested that even in tetanus the typing of the bacillus might be of importance in that infection of a non-disease-producing nature with one "type" already existing in an animal precluded an infection capable of producing disease by that same "type" in that animal, although infection and disease production

due to another "type" might well occur. The second point was of a purely practical nature and arose from Dr. Okell's remarks concerning the standardization of the toxin of, and antitoxin to, *S. scarlatinae*. Unless some species of susceptible animal was available for such standardization they must fall back upon *in vitro* tests. Notwithstanding the failure that had so far attended the application of a test similar to the Ramon test for the purpose in view Dr. Tulloch thought that further work on tests of this nature was indicated. When the extreme subtlety of all biological precipitation reactions was realized, a precipitation which occurred in colloidal systems of extreme complexity, it was obvious that much work would have to be done before concluding that a method of standardization based upon precipitation was valueless. He suggested, therefore, that in performing precipitation tests designed for the standardization of scarlatinal antitoxin a variety of electrolytes might be used for diluting the interacting reagents. The use of a suitable electrolyte might eliminate the difficulty which arose from false positive reactions, since non-specific agglutination, for example, occurred whenever the electrophoretic potential was reduced to + or -15 millivolts. There were certain electrolytes—phosphate buffer solution—which allowed specific agglutination to occur when the potential was much greater than the range + or -15 millivolts. He offered this as a suggestion to those engaged in the practical work of standardization of the reagents in question with the hope that it might prove of some value to them.

Dr. D. SAGE SUTHERLAND (Manchester) said that the practical application of the Dick and rash-extinction tests was of value in fever hospitals for purposes of control and disposition of cases. All cases of scarlet fever should be tested for the Dick and Schick reactions on admission, and at intervals of about seven days. A positive Dick reaction, becoming negative in two or three weeks, was confirmatory of the diagnosis; the persistence of a positive reaction beyond this period would make one regard the case in a more critical manner. The convalescent serum in such cases might then be tested as to its rash-extinction producing properties on undoubted cases of scarlet fever with controls. The application of the Dick test in cases of diphtheria on admission was of assistance in the differential diagnosis of serum, enema, and scarlet fever rashes, or the occurrence of faint rashes of doubtful nature should such occur during the period of convalescence. On the accidental introduction of scarlet fever to a diphtheria ward a knowledge of the most susceptible patients (those giving positive Dick reactions) was at their immediate disposal; passive immunity might be established in these cases without delay by injection of prophylactic doses of immune serum. Discharge of cases and control of infectivity by bacteriological examination for demonstration of the absence of *S. scarlatinae* would be difficult to carry out in hospitals without the assistance of a special pathologist on the staff.

Dr. PENFOLD asked Dr. O'Brien whether he would give details of the "suitable broth" he had mentioned as a culture medium for *S. scarlatinae*. He would like to know the percentage loss of antibody during concentration of the serum. He also asked whether it was possible to produce nephritis in animals.

Dr. DONALDSON asked Dr. O'Brien to what extent the so-called *Streptococcus scarlatinae* had been found responsible for the septic complications following scarlet fever. Far from having been converted to the view that scarlet fever was caused by the *S. scarlatinae*, the facts which he had heard rather suggested that the true primary cause had not yet been discovered. The disease seemed to have points of close analogy with swine fever, where the actual virus was usually accompanied by a bacillus. Dr. Donaldson suggested that possibly the *S. scarlatinae* might be regarded as an indicator of scarlet fever rather than as its cause, in the same way as *Bacillus suispestifer* might be regarded as an indicator of swine fever. The *S. scarlatinae* bore a very close relationship to scarlet fever, but they must not be induced on those grounds alone,

however strong the temptation might be, to accept it as the cause. From the point of view of science its claim had not yet been established.

Dr. FLOID asked whether there was any explanation of the well known fact that the type of scarlet fever had become much milder in recent years.

Dr. O'BRIEN, in closing the discussion and in answer to questions, said that the work of Dr. Parish seemed to show that a good scarlet fever antitoxin would consistently protect a rabbit against a lethal dose of culture of *Streptococcus scarlatinae*, both being given intravenously, while a poor serum would not. The immunization of nurses was already being practised in England with, so far, very promising results. It was at present premature for the bacteriologists to claim to speak with authority to the public health administrator and tell him which people were potential carriers—that is, distributors of scarlet fever. Dr. Trevan had tried the effect of scarlet fever toxin on the capillary loops of the intestine, but could not find any consistent effect. He agreed with Professor Douglas that the absence of research in infectious fever hospitals was lamentable, but hoped that the appointment of the pathologists to the Metropolitan Asylums Board and also, probably, to the fever hospital in Manchester, would mark the commencement of a time when the amount of clinical pathology in infectious fever hospitals would be comparable with that in large teaching general hospitals. He felt that if the antibacterial serum made by the injection of streptococci could be of any use, that fact would have been discovered during the many years that antistreptococcal serums had been used for the treatment of scarlet fever. He was, however, at present disinclined to hope much from antibacterial scarlet fever serum. He had concentrated scarlet fever serum on a large scale; apparently considerable losses occurred if the routine processes were used, but it was very difficult to check the loss, since the present methods of titration were so difficult to command and so liable to fallacy. The speaker now fully accepted the *Streptococcus scarlatinae* as the cause of the disease. If belief was retained in a filterable virus it was necessary to show that "subcultures" through many generations of Dick "toxin" must still produce the "Dick reaction," and, further, it must be assumed that the virus survived and grew *pari passu* with the streptococcus through many generations in artificial culture, for antitoxin made by injecting the toxin of the streptococcus subcultured for several years was specific.

### THE ETIOLOGY OF ERYSIPELAS AND ITS SPECIFIC THERAPY.

BY

KONRAD E. BIRKHAUG, M.D.,

New York.

[Abstract.]

Dr. BIRKHAUG said that two years ago he was able, by means of agglutination and absorption tests, to show that 91 per cent. of erysipelas strains of haemolytic streptococci isolated from typical erysipelas lesions fell antigenetically into one group, and that this group could be readily distinguished from other types of haemolytic streptococci. He then produced erysipelas experimentally in rabbits. The pathological condition closely resembled that seen in human erysipelas. He found that intracutaneous infiltration of immune erysipelas serum with *Streptococcus erysipelatis* prevented the development of lesions. Subcutaneous or intravenous administration of the serum protected the animals against lethal doses of *S. erysipelatis*, but not against other streptococci. In a study of the toxin produced by the erysipelas organism he found that a skin test dose of 0.1 c.cm. of a 1 in 1,000 dilution of the toxic filtrate produced in susceptible persons a lesion similar to that found in the Schick and Dick tests. This lesion was neutralized by mixing the skin test dose with an equal amount of convalescent erysipelas serum or with 0.001 c.cm. of immunized rabbit or donkey serum.

Dr. Birkhaug had then set to work to try the effects of erysipelas antistreptococcal serum on clinical cases. For

this purpose he immunized a donkey and a horse according to the method of Dochez. Up to the present the treatment had been tried on sixty patients. The average dose was 100 c.cm. of the unconcentrated and 15 c.cm. of the concentrated serum. In only eight cases was more than one dose given. The most marked effect was the prompt improvement of the toxic depression of the patient. This was followed, if the serum had been given early enough in the disease, by an almost critical drop in the temperature and the rapid disappearance of the erysipelas lesion, together with the accompanying oedema and blebs. Dr. Birkhaug showed a very interesting series of lantern slides of erysipelas in rabbit and man, illustrating the effects of treatment.

## DISCUSSION.

Dr. OKELL said that the reactions obtained in the rabbit with the *Streptococcus scarlatinae* resembled those of Dr. Birkhaug with the erysipelas organism.

Dr. O'BRIEN raised the point as to whether the serum was antibacterial as well as antitoxic. Work had been done in Russia twenty years ago on the streptococcus of scarlet fever. But the serum they made was antibacterial, produced by the injection of cocci, and was apparently not antitoxic. If this serum had been of value in the treatment of disease it would have long ago come into general use; antibacterial serum was conceivably of no value. The antitoxic serum probably contained all that was required.

Dr. BIRKHAUG, replying, said that it was Dr. Park's experience that horses immunized against *S. scarlatinae* produced a serum highly antitoxic during the first six months of immunization, but that the serum first became bactericidal after eight months. The same held true of the erysipelas antiserum. It had been interesting to note that patients having recurrent attacks of erysipelas had been actively immunized intramuscularly. It was premature to judge the persistence of this active immunity, but so far this had lasted six months in individuals who previously had attacks every six to eight weeks. They might find that this active immunity followed the same lines as diphtheria toxin-antitoxin immunity, and recently scarlet fever.

COMYNS BERKELEY, M.D., M.Chir., F.R.C.P., President.

## DISCUSSION ON THE PLACE OF INDUCTION OF PREMATURE LABOUR IN THE TREATMENT OF CONTRACTED PELVIS.

### OPENING PAPER

BY  
J. BRIGHT BANISTER, M.D., M.R.C.P.LOND.,  
F.R.C.S.ED.

Consulting Obstetric Surgeon, Queen Charlotte's Maternity Hospital; Assistant Obstetric Physician, Charing Cross Hospital; Surgeon, Chelsea Hospital for Women.

A PERusal of the annual reports of maternity hospitals brings to light the frequency with which Caesarean section is performed in the management of cases of pregnancy complicated by contraction of the pelvis, while in the last few years much valuable information has been obtained as regards the dangers, after-results, and subsequent labours attending or following the operation. I confess to a growing suspicion that Caesarean section is being employed oftener than is justified in the presence of, or in the anticipation of, difficulty in labour due to pelvic deformity, and I am grateful to the officers of this Section in that they have done me the honour of asking me to open a discussion upon the place of induction of labour in cases of contracted pelvis. I stand here as a sinner who has repented,

knowing that in the past I have been guilty of performing Caesarean section more often than a ripper judgement would allow me to do to-day, and conscious that there is more in the treatment of labour in cases of contracted pelvis than the employment of Caesarean section. I am convinced that the operation of induction of premature labour has fallen into unjustifiable disrepute, and that it can be employed with success in many cases where a Caesarean section is now done.

This discussion does not embrace any consideration of the methods of inducing premature labour, for those in use to-day are perfectly simple and straightforward.

The conclusions put before you to-day are based upon an analysis of 745 cases of induction of labour for contracted pelvis carried out at Queen Charlotte's Hospital, Charing Cross Hospital, and in my own private work. I should, therefore, like to thank my predecessors and colleagues at those institutions for their kindness in allowing me to use their records.

The first consideration in advising any procedure which departs from the normal is the danger to the mother of the means suggested. In this connexion the series under review contains one maternal death, which occurred from a pulmonary embolism on the twelfth day. This gives a maternal mortality of 1.3 per 1,000, which certainly absolves the method of any abnormal risk.

Next the danger to the baby must be taken into account, both as regards the delivery and as regards its chance of survival. In this series there were in all 99 foetal deaths, 56 of these being neo-natal and 43 post-natal in occurrence. This high mortality must be corrected by the subtraction of 5 cases in which the cause of death was wholly unconnected with the induction of premature labour. The causes of death in these cases were placenta praevia, foetal ascites, deformity of heart, exomphalos, and eclampsia. We have, therefore, 94 deaths in the series up to one month after birth, which gives a mortality of 12.6 per cent. A closer examination of the enormous advance of obtaining a natural delivery if possible. In 589 cases in this series unassisted delivery was accomplished, with a foetal mortality of 50. This gives a percentage mortality of just under 8.5 per cent. On the other hand, 132 cases were completed by forceps delivery, and of these 31 babies died before the end of the first month. This gives a percentage mortality of 23.4 per cent., amply demonstrating the danger attending the use of forceps in delivering premature infants. Yet another point worthy of mention in considering the infant mortality attending induction is the position of the baby at the onset of labour. These cases show that the incidence of posterior positions of the vertex is relatively much greater in labours resulting in the infant's death than in those cases where the child survives.

The relation between the date at which induction is carried out and the result to the baby is generally stated to be that the mortality rate drops as the date of induction advances, and this is borne out by the results in the series under review, with the exception that the inductions carried out at or near term show a greater mortality rate. This we must frankly attribute to the fact that the induction was sometimes delayed too long.

In 24 cases the method failed, and either embryotomy or Caesarean section had to be adopted. There are in the series 5 cases in which perforation was required, some of these being followed by craniotomy, and 8 cases where the labour was terminated by Caesarean section. In all these last a live baby was obtained and thrown, while the mothers all made uninterrupted recoveries.

Turning now to complications encountered, we find that the morbidity rate is no higher than that obtaining among normal deliveries. In this series 29 patients had a pyrexial puerperium, giving a morbidity rate of just under 4 per cent. In a few cases a certain amount of haemorrhage is noted to have occurred after the introduction of bougies, but this was never serious.

In 12 cases the cord prolapsed, and this accident was in this series, attended by a very high foetal mortality, no fewer than 9 of the children being born dead. This prolapse seems to me to be the most important complication

from the foetal point of view, but may be attributed to the pelvic contraction as much as to the premature induction of labour.

These 745 cases show, I think, that premature induction of labour presents a safe method as far as concerns the mother, and in favourable cases gives good foetal results. It remains to suggest the application of the method in regard to, first, those cases suitable for its employment, and secondly, the choice of the time for carrying it into effect. Ante-natal examination is now an integral part of the duty of practitioner to patient, and one would assume that the first examination is carried out during the mid weeks of pregnancy. The presence of pelvic deformity is now recognized and the degree of contraction noted. If on measurement of the given pelvis the true conjugate is calculated to be  $3\frac{1}{4}$  in. or less, induction of labour is contraindicated. It is certain that with a pelvis of this size or smaller there is but little chance of delivering naturally a child of sufficient size to have any real prospect of survival, and the rational treatment will be to perform a Caesarean section at full time. When, however, the pelvis is found larger than this, the question of induction may be considered, and the next problem to be solved is the optimum time for the operation.

There is no doubt that the choice of the best time for induction of labour in a case of contracted pelvis calls for repeated careful investigations by the practitioner in charge. Two main points have to be considered—that is, the relative sizes of the presenting part and the pelvic brim, and the shape of the pelvis. In addition, but subsidiary to these, is the position of the child's head.

In order to appreciate fully the points which lead us to a decision frequent examinations are imperative. It is not too much to say that these patients should be seen every week, and that the relation between the child's head and the pelvic brim should be investigated each time. The shape of the pelvis may be of no small value in gauging the time for induction of labour. If I might generalize, I would say that a pelvis contracted in all directions presages an earlier induction than one in which the deformity consists of a flattening.

Should the contraction be oblique, the position of the occiput must be accurately known. If this be upon the contracted side, the mechanical difficulties of delivery will be greatly increased and induction should be carried out relatively early; if it be found on the wider side, the mechanical conditions are in favour of delivery, and induction may be accordingly delayed.

By far the most important clinical investigation is the determination of the coaptation of the child's head to the pelvic brim—the endeavour of the practitioner to answer for himself the question, "Will this head go through this pelvic brim?"

Whatever method be used, we endeavour by bimanual examination to obtain an appreciable descent of the head through the brim, and if this descent is achieved we can with safety consider that induction may be postponed awhile. At weekly intervals this examination is repeated until the time comes when descent is doubtful. At this stage an examination under anaesthesia is of very great assistance, for by this means the conditions present can be most fully determined. It has been my experience that examination under anaesthesia at this time nearly always leads to the conclusion that the disproportion is not so marked as was thought before the anaesthetic was given. Should this happen, it is my practice to advise induction in fourteen days' time, provided the pregnancy has advanced to thirty-five weeks. Should the result of examination be that only a small amount of movement be obtained, I would advise induction in one week—again with the same proviso as to the length of gestation. If the head cannot be made to engage at all, but there is no real overlapping at the upper border of the symphysis pubis, the indication is towards immediate induction. As was pointed out by the present Master of the Rotunda Hospital, experience brings to all of us an increased belief in what Nature can accomplish in dealing with cases of contracted pelvis, and it is this reliance on her power that enables us to wait to induce labour until the head will just not enter

the brim, always provided that we see the patient at short enough intervals.

Certain special points may also be noticed during this complete examination relating to the position and attitude of the head. For example, in dealing with a generally contracted pelvis, if the head is noticed to be well flexed and in an occipito-anterior position, induction may be safely advised, although manual efforts may not be able to produce much descent; while, to take another example, if in a flat pelvis the sagittal suture is felt to be definitely nearer the symphysis than the promontory, and the child's head more extended than flexed, it is doubtful whether induction should be recommended at all.

It may be said that these frequent examinations, and particularly the employment of anaesthesia, will be resented by patients, and even that they will refuse to submit themselves to them. I do not believe this to be true in the majority of cases, for the tendency to-day is for prospective mothers to demand ante-natal care, and protection from the difficulties of childbirth. Moreover, a frank explanation of the reasons for the frequent examinations will remove any resentment which might possibly be shown, and will prove to the patient that the object is to ensure, if possible, a natural labour and delivery. If this be gained, surely the discomfort of several ante-natal examinations and an anaesthetic is but small cost. Again, it may be urged that these preliminary investigations require time which the busy practitioner can ill afford; but in reply it is surely fair to suggest that upon the opposite side of the account we may place the saving of the time and mental wear and tear which accompany a long and difficult extraction through a small pelvis.

May I suggest, too, that in the employment of induction of premature labour we can obtain evidence of incalculable value as to the capacity of the particular uterus to deliver itself of children? The trial labour has been spoken of on many occasions, and it has very many advantages. If such a trial labour be arranged at a carefully calculated date, we are surely using it in its most advantageous form, and we shall obtain therefrom most valuable knowledge as to what one might perhaps term the capacity for delivery of a particular patient. We obtain it, it is true, at a certain risk to the life of the child, but we have the consolation of knowing that we also obtain it at a risk to the patient one-tenth as great as that involved in Caesarean section (putting the mortality as low as 1.3 per cent.), from which is gained the possibilities of non-

The knowledge subsequent pregnancy and labour, renders the task of deciding upon the means to be adopted very much simpler. At the best we may discover that a patient is capable of delivering herself with infinitely greater ease than we either expected or hoped, and as a result we may be able to leave the next pregnancy to go to full term. Conversely, we may find more difficulty than we expected, and may have to revise the procedure on a subsequent occasion.

"Once an induction always an induction" is not a true saying. On each occasion the same care in investigation is necessary, together with a careful interpretation of the evidence gained at previous confinements. Every induction of labour, even in the same patient, must be justified by a consideration of the attendant circumstances, and the fact that a patient has had an induction before cannot be accepted as anything but presumptive evidence.

Within the last month I have had news of a patient who had her first child by induction at the thirty-sixth week in three hours from the onset of pains, her second by induction at the thirty-eighth week, and her third and fourth at full time, the last child weighing 8 lb. 2 oz. According to my investigations, she has a flat pelvis with a calculated true conjugate of just over  $3\frac{1}{4}$  inches.

Finally, the points I would leave with you are these. First, that the wider use of induction of labour in cases of contracted pelvis should be urged, and that this is especially necessary to-day in view of the widespread employment of Caesarean section. It should be urged because it is simple, safe, and unaccompanied by untoward complications and sequelae.

## INDUCTION IN CASES OF CONTRACTED PELVIS.

Secondly, that premature induction of labour is not to be decided upon lightly, but should be dependent upon very careful investigation and frequent examination.

Thirdly, it affords the only actual test of the power of a given uterus under conditions which imply a reasonable chance of the survival of the baby.

Last, but not least, it is an attempt to procure what is rightly regarded as the highest aim of the true obstetrician—a natural parturition.

## GENERAL DISCUSSION.

Dr. RHODA H. ADAMSON (Leeds) said that the question of induction of labour as a form of treatment of contracted pelvis depended in the first instance upon the degree of contraction, and secondly, upon the shape of the sacrum. regards general deformity and also the tilt of the district in which she practised varied very much with the social position of the patient. Her private patients mostly had symmetrical pelvis, and if they were contracted they fell under the heading of "small round pelvis." Her hospital patients were drawn from an urbanized community, brought up under poor housing conditions and suffering from the result of infantile rickets. The infant welfare movement was in its early days when she was appointed to the staff of the Leeds Maternity Hospital fifteen years ago, and the result of its work was not yet apparent in the better physical development of their present hospital patients. They had, therefore, many cases of contracted flat pelvis as well as the simple flat variety; the classical type of small round pelvis formed only a small proportion of their hospital cases of pelvic contraction. The small flat pelvis as she had seen in her practice for any treatment except that of Caesarean section, as the pelvic inlet would not permit of the passage of a viable child. The simple flat pelvis had in her practice given rise to most surprisingly good results when left alone and allowed to go into labour at term, the presenting head having engaged somehow in the only diameter of an asymmetrical pelvis through which it could pass. She had a patient who was on the black list of the local supervising authority of the Central Midwives Board, having lost her first three children as a result of difficult and instrumental delivery for her flat pelvis. Dr. Adamson had had this patient under her care with her fourth and fifth labours. On both occasions she had been prepared for Caesarean section; and both times she had delivered after a few hours, the frontal region having slipped into the recess to one side of the sacrum after labour had started. In Dr. Adamson's opinion the type of case that was best treated by induction of premature delivery was one in which there was a moderate degree of general contraction, when the head could still be pushed into the pelvic inlet at the thirty-fifth or thirty-sixth week of pregnancy. It was worth remembering that the child's head tended to resemble in shape and hardness the head of its father, and that in the case of the *petite primipara* with a small round pelvis it was worth while having some personal knowledge of the size and build of the husband. Dr. Adamson considered the actual measurements of various diameters of far less importance than the relative fit of the presenting head at the inlet. She had no personal experience of induction before the thirty-fifth week, as she felt that at an earlier date the strain of a long labour equal to that at full term with a normal pelvis.

Dr. J. S. ENGLISH (Singapore) had always found that a careful vaginal and external examination, together with Munro Kerr's method of estimation of relationship of the head and pelvis, were of a great deal more value in estimation of the date of induction than a measurement of the exact size of the pelvis by a Skutsh pelvimeter. It frequently happened that a 7½ lb. baby was delivered through an 8.5 to 9 cm. pelvis, and in other cases a 7 lb. baby was arrested in a 9.5 to 10 cm. one. He suggested that when a physician had had any trouble with a confinement the patient should be given a history of the case in order to guide another in the conduct of her future labours.

Professor LOUISE McILROY (London) said that in ante-natal work it was essential to ascertain the date of the pregnancy so far as possible, since mistakes might be made as to the exact time when induction of labour was performed. An immature infant might die in labour from prolapse of the cord, or it might be brought into the world and survive only a short time. For this and other reasons it was better to perform Caesarean section at labour. There was better contraction of the uterus, less risk of haemorrhage, and by giving labour a trial Caesarean section was often found to be unnecessary, even in cases where the head would not enter the brim until just before expulsion of the child. In one patient sent for advice as to the possibility of the continuation of pregnancy in a case of marked spinal deformity, and where Caesarean section seemed the only method of delivery possible, the patient had a normal pregnancy with the exception of a pendulous abdomen. Labour, however, unexpectedly occurred before term, and the patient was brought into hospital and delivered herself of a small but healthy child without even the use of forceps.

Induction of premature labour should never be considered before the thirty-sixth week of pregnancy, and in the majority of cases the thirty-eighth week gave good results where Caesarean section was out of the question. The difficulty in most labours in minor degrees of generally contracted pelvis as seen in London was not only in the size of the head but in the failure of flexion. If manual rotation of the posterior occiput and flexion of the head was performed in labour, or, if possible, in late pregnancy by the abdominal route, many cases of difficulty and delay in labour could be avoided. Cases of failure of the head entering the brim could be estimated to some extent, but the chief difficulty lay in cases of contraction of the outlet where complications only arose when the presenting part arrived in the cavity of the pelvis. Although a general estimate of the contraction could be arrived at there was no definite method of accurate measurement yet invented. The difficulty would always be to estimate the size of the outlet with that of the presenting part. In a case of breech with extended legs it was extremely difficult to give any prognosis as to the character of the future labour. In the majority of cases version failed when an attempt was made to bring the head into approximation with the pelvis for the process of estimating their relations. More attention should be paid to the conduction of labour. The patient should not be urged to strain or pull on any fixed object, as the work entailed caused fatigue of the uterus and loss of contractions. Sedatives should be given and labour should be allowed to take its course. If mother and child were well there was no need to hurry, no matter how busy the medical attendant was. The administration of morphine was very beneficial in avoiding fatigue; the use of pituitrin was dangerous. Post-maturity was sometimes a cause of difficulty in labour in a slight degree of pelvic contraction, and induction of labour in these cases would save a considerable number of infant lives. The size of the father's head was a very important point when dealing with a mixed race such as the Anglo-Saxon. The relative sizes of the parents was also given consideration in stock-breeding farms. In young pregnant girls Caesarean section should not be performed for a small pelvis, since the pelvis was not fully developed until after 18 years of age. Repeated vaginal examinations during pregnancy were as a rule unnecessary except for special indications. Obstetrical patients seemed to object more than gynaecological to examination. This in itself might be protective, and indicated that as few as possible should be made; abdominal palpation and external measurements were sufficient in the majority of cases. The methods of induction varied, the most satisfactory one, apart from drugs, being the flexible rubber tube. X-ray plates showed that the tube reached the fundus, and by coiling up between the ovum and the uterine wall proved a very effective irritant to the uterus.

Mr. HUNTER EVANS (Newcastle-on-Tyne) thought that Dr. Baister had established the value of induction of premature labour in cases of contracted pelvis. As one who did a great deal of ante-natal work, the practical difficulty

which he encountered was the sorting out of the border-line case. The gross case was generally obvious, but the pelvis with a true conjugate above  $3\frac{1}{2}$  inches was somewhat difficult to sift. In the multipara they could be guided by the previous obstetrical history, but the real problem was the primigravida with the border-line pelvis. If the head was above the brim of the pelvis at the thirty-sixth week a vaginal examination should be made to determine the internal pelvic measurements as well as to get the head to the brim. External measurements might be a useful guide, but the ultimate result would depend upon the fit of the head to the brim. His investigation of 150 cases of head above the brim in primigravidae with slight degree of contracted pelvis showed that about 12 per cent. came to Caesarean section. Undoubtedly a large number of these cases would have been unnecessarily induced, but induction would have saved some unnecessary sections. In his opinion the greatest trap was the asymmetrical pelvis. Where the contraction was of the simple generally contracted or the simple flat variety estimation of the fit of the head to the brim could be fairly accurately gauged. This, however, did not apply to the asymmetrical case.

Mr. L. C. RIVETT (London) drew attention to the importance of recognizing the relative proportion of the head to the pelvis. He emphatically agreed with Dr. Adamson that the size and build of the husband might have an important bearing on the size of the child. He stated that small women usually had small babies, and that in consequence the actual measurements were not as important as the proportion. He had observed several cases of very fat women, in whom he thought that fat in the sub-peritoneal tissues and in the obturator fossae might be a factor in reducing the available room in the pelvic canal, and gave details of a case he had treated by Caesarean section of a woman, aged 22, who weighed 15 st. He had noted that third, fourth, and fifth babies were often of larger size than the first two, and pointed out the importance of ante-natal examination of all multigravidae. After induction the duration of labour was an important guide when taken in conjunction with the weight of the baby. He advised that all patients in whom the pelvis was below normal should be given a note stating the duration of labour and the birth weight of the child, for the guidance of the practitioner who attended future confinements. He emphasized the importance of recording the correct weight, and described how erroneous weights might be given by the patient. He quoted some figures from Queen Charlotte's Hospital giving the foetal and neo-natal death rate after induction, showing the optimum time to be the thirty-eighth week and the great increase before the thirty-sixth week. He drew attention to the danger of allowing a patient with a small pelvis to go over time.

Mr. S. W. MASLEN JONES (Wolverhampton) stated that the previous speakers had all presumed due provision of maternity beds and supervision, and that the problem of induction assumed a different aspect when such a service was not available. He had not found the castor oil and quinine method very efficacious in inducing labour before term, and felt that the family doctor was averse to undertaking mechanical induction as a rule. He thought that induction by such methods as the stomach tube or bougies could be safely undertaken in private, as opposed to institutional, practice, and that the little trouble involved by this procedure would be more than compensated for by the ultimate saving of time and anxiety, quite apart from the avoidance of permanent after-injury to the mother and the production of an uninjured child.

Mr. A. B. DABY (Birmingham) said that after a long experience of ante-natal work he had come to the conclusion that the actual measurement of the diagonal conjugate was of little importance, and that the most important single method of examination was "fitting the head," which he usually did at the thirty-fourth week, although it was his practice never to induce labour before the thirty-sixth week. He wished to draw attention to the fallacy of fitting a deflexed head, very often associated with an occipito-posterior position, which in a number of cases would not enter the brim of the pelvis. When, however,

the position was converted into an occipito-anterior by the pad and binder method of Buist, he had found that in a large number the head would enter quite easily. As regards the point raised by Dr. Adamson and several other speakers as to the relative size of the father to the mother, he was of the opinion that the cardinal point was the size of the paternal head, and his maxim had been that "a man with a large head should never marry a woman with a small pelvis." Mr. Danby said that in any discussion on the induction of premature labour it was of vital importance to know the methods employed in this procedure, and he hoped that Mr. Banister, in his reply, would give them details as to his technique and the length of time occupied in inducing labour. At the Birmingham Maternity Hospital it had been the custom to induce these cases with a Jaques solid rubber oesophageal tube, size 14, instead of the usual stomach tube, the technique employed being the same as that advocated by Gibbon FitzGibbon at the Robunda Hospital. In his experience it was a more certain and quicker method than employing Krause's bougies, when the average interval between the introduction of the bougie and delivery of the child was usually estimated at seventy-two hours. From an analysis of the figures of this hospital it was found that in the last 20 cases induced by the modified stomach tube method, over 35 per cent. were delivered within twenty-four hours, and 60 per cent. within forty-eight hours. In 10 per cent. of cases it was unsuccessful; Caesarean section being subsequently performed, and in no case did the induction-delivery interval exceed seventy-two hours. Touching upon the quinine and castor oil method of induction, an analysis of 38 district cases where it had been employed showed 68 per cent. of successful cases and 32 per cent. of failures. He had no record of the induction-delivery interval in this series, but was informed that in a number of cases the procedure was repeated on several occasions, and that it was most successful at or about term.

Mr. T. H. RICHMOND (Stoke-on-Trent) said that, like Mr. Maslen Jones, he was in practice in Staffordshire, where, so far as he knew, there were no maternity or ante-natal beds. Therefore they had no opportunity of making an extended investigation as to whether the patient could be allowed to deliver herself or intervention would be necessary. His method, if the woman gave a past obstetric history or there was any doubt, was to induce at the thirty-sixth week. He had had good results with the use of pituitrin at term, as recommended by Professor Blair Bell to prevent post-maturity.

The PRESIDENT entirely agreed, as the result of his experience at the Middlesex and City of London Maternity Hospitals, that induction of labour was far safer than Caesarean section in the cases which they had been discussing. He thought that safety was much greater than had been stated by Mr. Banister, who gave the mortality of Caesarean section as 1.3 per cent. After all, this figure had reference more to the work of experts. Medical students were so well taught nowadays that many more operated than in the past. If such a body of expert opinion as was present had declared themselves in favour of Caesarean section, naturally such advice would be relied upon, and the mortality of Caesarean section would go up by leaps and bounds, since while the induction of premature labour was a comparatively simple operation, the operation of Caesarean section required for its safe performance and result much experience and skill. The President asked Mr. Banister if he had had any experience of the administration of pituitary extract as an aid to other methods of induction. He had always fancied that the drug did not act till labour started, and yet he had heard that it was the custom to sensitize the uterus, in some quarters, with repeated small doses the week before the insertion of bougies. He had never had any personal experience of this drug in these circumstances, but he knew of a case in which bougies had been inserted to start labour, and because it did not start satisfactorily an injection of pituitary extract was given, leading to rupture of the uterus and death of the patient. Just as the death of so many children at term was due to the untimely use of the forceps, so he wished to warn practitioners against using the forceps to hasten

delivery in a labour that had been induced. Most of the deaths during premature labour that he knew of had been due to such a procedure. Nature moulded the head much better than the obstetrician could with the use of instruments. There was very little harm, so long as some progress was being made, in allowing the second stage to continue beyond the classical time, and a premature head was more likely to suffer from rapid extraction than one at term. He agreed that with an estimated conjugate of  $3\frac{1}{4}$  inches and under induction of labour was contra-indicated, not only because of the great foetal mortality at birth which had been mentioned, but also from the fact, which they should all bear in mind, that, according to the statistics of the Tarnier Hospital in Paris, taking those children who were born apparently healthy, nearly 80 per cent. were dead within a year. He always tried to induce at not less than thirty-six weeks, and otherwise as late as possible up to term. Several speakers had mentioned the importance of the relative sizes of the parents. A good example of this was that in African, and probably other semi-savage tribes, difficulty due to disproportion between the head of the child and pelvis of the mother was practically unknown, and in most of the cases in which such obstruction had been encountered by medical men, it was due to a white man having impregnated the black woman. Some of the speakers had stated that they placed no reliance on external measurements of the pelvis. The commonest form of abnormal pelvis in London was that of general contraction, and the most difficult cases he had met with were in those who had not been to an ante-natal centre and in whom the head entered the pelvis, so that everything was thought to be all right. Later, however, it was found that the head would not pass out of the pelvis. He thought a knowledge of the external measurements of the outlet of the pelvis was very important. Such measurements might be very difficult or impossible to take accurately, but an idea could be obtained by a comparison with one's fist or a tape measure, and so a warning of the greatest importance might be given. He never examined a patient vaginally with the object of ascertaining the size of the pelvis before the thirty-sixth week. In the first place, no object was gained, since if the head would not enter the pelvis then it was a case for Caesarean section; and secondly, an examination before this time might be followed—*post hoc*, not *propter hoc*—by a premature labour or miscarriage, for which the doctor would surely be blamed.

Dr. RHODA ADAMSON, in replying, said that when she was not certain whether the head would enter the brim or not she generally tied a tight binder before making an examination under an anaesthetic. Quite a number of her patients were never submitted to vaginal examination at all; she preferred herself, and taught her students, to rely more upon examination per rectum. She agreed with the President that no extensive examination was advisable before the thirty-sixth week. In regard to the methods of effecting induction, she had not found castor oil and quinine effective before the thirty-eighth week. She confessed she was rather frightened at the ante-partum use of pituitrin. Up to three years ago she had used bougies, since then she had used a stomach tube. If, as sometimes happened, a patient could not be induced by these methods, the alternative was Caesarean section. It was very difficult to obtain the accurate weights of babies at birth; she had found the weight of the child generally increased up to the mother's thirtieth year and then remained stationary or decreased. She had had two patients who delivered themselves spontaneously after Caesarean section.

Mr. BANISTER, in his reply, took strong exception to the saying, "once a Caesarean, always a Caesarean." In quite a number of cases where Caesarean section had been performed for the first baby, subsequent children had been born easily with induction. With regard to contraction at the outlet, this was very definite but comparatively rare. Of 900 cases of contracted pelvis, in 8 only was the contraction at the outlet the predominant feature. A head in the vagina with the patient under an anaesthetic would enable an estimation of the condition

at the outlet to be formed, though it would not give a measurement in inches or centimetres. He looked upon a breech with extended legs occurring in a primipara with pelvic contraction as a *suré* indication for Caesarean section. He advocated external measurement of the pelvis at an early date, but every vaginal examination on the pregnant woman must be justified and no such examination should be done earlier than the thirty-fifth or thirty-sixth week. He was strongly opposed to rectal examination being used in place of vaginal. He had employed most of the methods for inducing labour. At full time castor oil and quinine gave a fair measure of success, but it was useless for the induction of premature labour. He relied upon Krause's No. 12 gum-elastic bougies, usually inserting three. With the patient in the lithotomy position, after the usual toilet had been carried out, the bougies could be easily passed directly into the cervix, which had been drawn down by a vulsellum. No douching or plugging or other after-treatment was necessary or advisable. The time for labour to be completed was on the average fifty-four hours in primiparae and forty-seven hours in multiparae. Since the introduction of the 10 per cent. solution of pituitrin he had had good results by injecting  $1\frac{1}{4}$  c.cm. every hour till 1 c.cm. had been given in cases where no pains came on within ten hours of the insertion of the bougies.

## Memoranda:

### MEDICAL, SURGICAL, OBSTETRICAL.

#### THE FILLED DEAD TOOTH AS A SOURCE OF STREPTOCOCCAL BLOOD INFECTION.

THIS case is recorded not merely because I have so far been unable to find a similar case in the literature, nor yet because it is interesting, but with the object of discovering other cases and so establishing its identity. A symposium on this subject will be held at the Post-Graduate Hostel on October 28th, when it is hoped that cases will be brought forward either personally or in writing.

The patient was a male, aged 29. The history probably dated from May, 1919. An attack of follicular tonsillitis was clearing up, when one evening there were peculiar pains in the left ankle. The following day these had ceased, but the ankle was swollen and pitted on pressure. The patient did not go to bed until "tightening" pains of the lower part of the right chest and considerable constitutional disturbance, temperature  $101.5^{\circ}$ , ensued. No urinary symptoms or albuminuria were present. The pains in the chest gradually disappeared in six weeks, but the oedema increased, extending up the leg, but never affecting the toes. There was no further pain in the ankle nor was there effusion, though it was put in plaster for four weeks on that supposition. Many diagnoses were made, of which the most likely was thrombosis of the posterior tibial venae comites.

The tonsils were removed one month later, and the appendix, which had become acutely inflamed, four months later. During the next four years the ankle frequently showed a slight oedema, though a crêpe bandage was worn constantly and usually sufficed to restrain it.

In August, 1923, the first of the attacks of erysipelatoïd occurred. A feeling of malaise and a temperature of  $101^{\circ}$  developed in about half an hour. Profuse vomiting occurred, lasting about twenty-four hours. The inguinal glands then became extremely painful, and in a further twelve hours the whole distribution of the saphenous vein was hot, painful, red, and swollen. The vein itself showed no signs of inflammation, not being hard; the affection was apparently of the accompanying lymphatics. The thigh and knee were fixed, preventing all walking. In a month the leg was quite normal.

Similar attacks occurred in June and August, 1924. In January, 1925, there was a mild attack; vomiting was much less noticeable, however. A second, even milder, attack occurred in May, when three injections of streptococcal vaccine were administered at four-day intervals; radiant heat was used during the attack. In August a very severe manifestation occurred, though vomiting and glandular involvement were slight. The leg was tender; all movements of toes and ankle were exquisitely painful; the course of the flexor tendons round the ankle was red, tender, and swollen. Mr. W. McAdam Eccles saw the case and suggested a dental focus of origin and advised having the teeth X-rayed, which was done, although unsatisfactorily.

In February, 1926, another attack occurred, but no vomiting; 40 c.cm. antistreptococcal serum was given. In April and June other attacks similar to the previous one developed. Dr. H. G. Adamson saw the patient; treatment by X rays was instituted, and the affected areas painted with a solution of silver nitrate in spirit. He advised re-examining the teeth, which was done at University College by Mr. McVillie; the films were referred to Mr. J. T. Carter. His diagnosis of an abscess at the root of the

second molar tooth was confirmed by Dr. Human, pus welling up from the infected root on removal of an apparently perfect filling. A strong antiseptic dressing was applied in July, and unless in eight weeks' time all sign of rarefaction has disappeared the tooth is to be removed. All the other teeth show large healthy pulp cavities. The tooth in question had not had root treatment, though three others had been so dealt with.

It is too early to predict a cure, but the patient has felt very much better since treatment to the tooth. One of the least explainable features was a distinct reduction in the slight permanent swelling of the ankle after an attack.

I suggest as a working theory that the first trouble was a venous thrombosis which, lowering the natural resistance of the limb, paved the way for the deposition of streptococci from the septic focus. The parts rendered vulnerable by previous attacks readily succumbed to a large dose of organisms set free from the tooth from time to time. They bore no direct relation to the first attack, which was venous in origin. The case, if it proves to be of dental origin, bears out the statement in a recent article<sup>1</sup> that it is the filled dead tooth which has not had its root treated, in otherwise healthy mouths, which is oftenest the source of constitutional symptoms.

Hotel, Russell Square, W.C.1. F.R.C.S.Ed.

### A CASE OF DIFFUSE TARISITIS.

LOCALIZED inflammatory infections of the tarsal plates of the eyelids are extremely common—for example, in Meibomian infections—but the following case of diffuse inflammation throughout the whole of a tarsal plate and confined to the plate is worthy of record.

A man, aged 22, consulted me, stating that a small swelling had appeared on the lid several months previously, but that during the month prior to the consultation it had increased rapidly. There was no pain and no tenderness. His chief concern was the disfigurement caused by the swollen lid, which was found to be greatly enlarged throughout its whole length; the swelling was slightly accentuated at the junction of the inner three-quarters with the outer quarter. Viewed from the side the lid had the appearance of a pendulous sac. The skin of the lid, which was somewhat tense, it could be easily picked up from the underlying tarsal plate, was bluish, due to compression of the venous return. The conjunctival vessels were engorged, especially over the accentuated swelling at the junction of the inner three-quarters with the outer quarter. The lower margin of the tarsal plate could be easily felt along its whole length, and the plate itself could be grasped by placing a thumb and forefinger at each end. By exerting a little pressure the plate could be felt as an elastic body with a large amount of "spring."

The accentuated swelling was incised on the conjunctival surface, but pus was not found, neither could any softened tarsal plate be removed with the sharp spoon. Hot fomentations were applied for one week, and as the swelling of the lid had not subsided it was again incised at the site of the previous incision. A small bead of pus was evacuated and also a small amount of softened tarsal plate. Since then the swelling has gradually diminished, the skin folds becoming visible in two weeks.

Two months after the second incision the lid had resumed its normal colour, and only a slight enlargement could be discerned on close inspection.

The diffuse inflammation in the plate itself was doubtless due to the primary infection in the Meibomian gland.

Honorary Assistant Surgeon, St. Paul's  
Eye Hospital, Liverpool.

### OVERDOSE IN SPINAL ANALGESIA.

REPORTED cases of overdose in spinal analgesia are so rare as to be worthy of record. For inducing spinal anaesthesia I had been using Barker's solution made up in 2 c.cm. ampoules, each ampoule containing 0.1 gram of stavaine and 0.1 gram of glucose in 34 minims of fluid. The average dose for an adult was 1.2 c.cm.—that is, 0.06 gram of stavaine, varying slightly with the age and physique of the patient, and the nature and the extent of the operation. When the supply of the preparation was exhausted the dispenser replaced it by another made up according to Chaput's formula, containing stavaine 0.1 gram, sodium chloride 0.1 gram, in distilled water 1 c.cm., which was the quantity each ampoule contained. I was informed that two ampoules of the new preparation contained the same amount of stavaine as one of the older, and acted on that information in the two cases here recorded.

<sup>1</sup> E. Sprawson, *Lancet*, August 7th, 1926, p. 300.

### CASE I.

A boy, aged 11, suffering from right inguinal hernia. He received 1.2 c.cm. of the solution (that is, 0.12 gram of stavaine instead of 0.06 gram), so that he had twice the usual dose. He became pale, retched, vomited, and showed all the signs of shock; the systolic blood pressure fell to 80 mm. of mercury. On the third day after the operation he was reported to have developed incontinence of urine, and I discovered that he had retention with overflow. A catheter was passed every eight hours, and soon afterwards the patient developed cystitis and haematuria. At times there was incontinence of faeces. Evidently there was complete paralysis of the bladder, with partial paralysis of the rectal sphincter. Electricity was applied to the spine, strychnine was given hypodermically, and urinary antiseptics and tonics were administered. After three weeks, control of micturition was partially regained, the cystitis and haematuria subsided, and the general condition greatly improved. Finally he recovered complete control of the bladder and the rectum, though he was left with frequency of micturition. I saw the boy again well over a year after the operation, when he was perfectly fit.

### CASE II.

The second patient, who was operated upon the day after the first one, was a girl, aged 19, admitted with acute appendicitis and abscess formation. She, too, received an overdose, as I had not by that time discovered the error. She exhibited a similar series of symptoms to those of the first patient, except that she did not develop cystitis. She suffered, at first, from frequency of micturition, but regained control in three weeks. I recently heard from her to the effect that she was perfectly fit and well.

The interest in the two cases is that a double dose of stavaine injected, owing to a misapprehension, into the spinal theca produced severe shock with retching, vomiting, and a marked fall in the blood pressure; and temporary, but complete, paralysis of the bladder centre in the cord, resulting in retention of urine with overflow and partial paralysis of the rectal sphincter, causing incontinence of faeces.

London, W.1. M. SOURASKY, M.D. Leeds, F.R.C.S.Ed.

### DIFFUSE ADENOCARCINOMA OF THE COLON.

THE following case of this condition occurred in our practice.

A man, aged 64, was first seen by us on July 10th. He stated that he had suffered two years ago from distension of the abdomen, flatulence, and vague pains. He was seen at that time by a surgeon who suspected colitis or malignant disease and recommended laparotomy, which was refused. He had since suffered intermittently from the same symptoms, which became more severe; he lost weight (about 3 st.) and observed lumps in the abdomen, which were described as "being here one day and gone the next." When seen by us he was weak from loss of weight and inability to take food, and suffered from pain all over the abdomen, diarrhoea, which consisted of blood-stained mucopurulent debris, and occasional sickness. The abdomen was generally distended, the bowel standing out in typical ladder pattern in both iliac fossae. A definite mass could be felt, about the size of the fist, round the umbilicus; it was elusive and receded from the palpating hand. In the epigastrium was a hard mass running transversely along the line of the transverse colon. Gurgling and splashing could also be elicited all over the colon. The abdomen was opened in the mid-line and a malignant condition was found inside the lumen of the bowel, involving the whole length of the colon from the caecum to the rectum; the muscular coat of the bowel could be freely moved over the mass inside, and polypoid masses could be felt even in the rectum.

The condition was taken to be one of a diffuse adenocarcinomatous infiltration of the mucous and submucous coats of the bowel, and the only action taken was a lateral anastomosis of the lower end of the ileum with the pelvic colon, with the idea of obviating the inevitable obstruction which must occur were nothing done.

### ADRENALINE IN CARDIAC ARREST.

WE read with interest the memorandum on adrenaline in cardiac arrest published on August 28th (p. 388). A fortnight ago we had a similar experience.

A boy suffering from a Colles's fracture was given an anaesthetic. When the fracture was set, and fully a minute after ceasing to administer the anaesthetic, the boy ceased breathing and the heart stopped beating.

Artificial respiration was without result. We then injected about 1/2 c.cm. of 1 in 1,000 adrenaline solution into the heart, and in fifteen seconds it was beating again.

The boy was apparently dead for at least sixty seconds.

MEMORANDA.

PT. 18, 1926]

PRIMARY ABDOMINAL TORSION OF THE  
GREAT OMENTUM.

SEPT. 18, 1920]

PRIMARY ABDOMINAL TORSION OF  
GREAT OMENTUM.

Mr. ERNEST COWELL' recently directed attention to the subject of primary abdominal torsion of the great omentum. He suggested that the condition is probably not so uncommon as the literature would lead the observer to believe. In this connexion the notes of the following case are of interest.

aged 46, of somewhat obese habit, was admitted to hospital on 12th day of illness. The onset was not acute; a dull pain in the umbilicus, and gradually increased to a severe pain in the right iliac fossa. The bowels acted normally. The temperature was 97.2° F. at admission.

A man, aged 46, of somewhat obese habit, was admitted to hospital after two days' illness. The onset was not acute; a dull pain began to the right of the umbilicus, and gradually increased in intensity. There was no vomiting, and the bowels acted as usual. The tongue was dirty. The temperature was 97.2° F. and the pulse rate 86. There was tenderness to the right of the umbilicus, and rigidity of the right rectus in the lower half. There was no tenderness over the umbilicus, and was regarded as an inflamed appendix wrapped up in omentum. Rectal examination afforded only negative information. The temperature and pulse rate were not inconsistent with the case being one of appendicitis. A diagnosis of subacute appendicitis was made, and operation performed forthwith. The abdominal cavity was entered through a right incision, the right rectus having been retracted in excess in operation. Incision, slightly smoky, was healthy. On sweeping the peritoneum, the appendix was entered, attached to the cecum.

[illegible]

Recovery was uneventful. No cause for the number of turns. In one recorded by Mr. Cowell, to represent the type. In before operation, between

This case is similar to the one recorded by the type. In and may fairly be taken to represent the type. In endeavouring to distinguish, before operation, between the omentum and acute appendicitis the following signs are of value. The appendix is not usually so acute

- endeavouring to reduce the omentum to its normal position. Torsion of the omentum is of value. Considerations are of value.
1. The onset of the illness is not usually as that of appendicitis.
  2. Pain and tenderness are located slightly higher than is usually the case with appendicitis.
  3. With torsion of the omentum pain is not so severe, and tenderness is not so exquisite.
  4. The twisted mass of omentum is, in many cases, palpable, and at a slightly higher level than a normally situated appendix wrapped in omentum.

**INFLUENZA ANTIGEN IN THE TREATMENT  
OF ENCEPHALITIS LETHARGICA.**

**INFLUENZA ANTIGEN IN THE TREATMENT OF ENCEPHALITIS LETHARGICA.**

AN interesting and valuable article by Dr. Crofton of Dublin on the causation and treatment of encephalitis lethargica appeared in the JOURNAL of March 27th, 1920. Dr. Crofton holds the opinion that the influenza bacillus is the cause of the disease, and in his communication adduces evidence in favour of this by giving the history of several cases of the malady which were cured by pure influenza antigen. To the perusal of his article are owing the highly gratifying results which followed the same method of treatment in the case of two patients suffering from the disease who have come under my observation.

CASE 1.

... had an attack of influenza in the second ... of his household ... before. So

A gardener, aged 58, had an attack of influenza in the second week of May, 1924. This complaint was very prevalent in the village in which he lived; two other members of his household (wife and lodger) had suffered from it not long before. Soon after getting about he began to complain of increasing weakness, and on May 20th he was found to have diplopia. These symptoms increased and then somnolence began to show itself. He would fall asleep at any time but was restless at night. He was treated with Easton's syrup, suprarenal extract, hexamine, and influenza vaccine (Parke, Davis and Co.), of which three hypodermic injections were given. The patient grew steadily worse, and on June 25th he seemed to be in a highly critical state. Incontinence of urine and faeces was present, complete, the patient being unconscious, and prostatic abscess was suspected. External unable to see anything unless an eyelid was raised. External

<sup>1</sup> Cowell, E.: *Brit. Journ. Surg.*, xii, 738.

strabismus of the right eye also showed itself and some time later the Parkinsonian facies; both of these have become permanent. There was also marked mental aberration, the patient occasionally thinking that he was busy "working with wood." An injection of influenza antigen, made from pure influenza bacilli isolated from cases who had or had had influenza, was given that day. Three days later incontinence of urine was present only when the patient was asleep, while he had more restless nights. On July 5th the fourth injection of antigen was given. The ptosis had now greatly diminished. Five days later, when the fifth injection was given him, he could count fingers correctly, while on July 22nd slight ptosis was present in the right eye only, he was able to walk about the room, and his mental condition was normal. Incontinence of urine had occurred only once, and that in sleep during the preceding week. On July 29th he was able to sit in his room for half an hour daily. The somnolence, which had been passing off gradually, was now slight; he might sleep for half an hour or so twice a day. The incontinence of urine had completely disappeared. From this time onward the patient continued to improve, though slowly. In the middle of October he was able to walk out of doors, and in January, 1925, to resume light gardening work, which he has been able to carry on to the present time.

CASE II.

A girl, aged 9, in the end of last May was rather suddenly seized with illness, the clinical features of which were drowsiness, severe headache, vomiting, and obstinate constipation. Some time later other signs appeared, and double optic neuritis, Kernig's sign, Brudzinski's "sign of the neck," and the temperature rose to 101°. There was leucocytosis of 42,800. On June 17th the patient was seen by Dr. Turton of Hull, who performed lumbar puncture. The cerebro-spinal fluid proved to be the same as "Mustretat and Rodriguez state is found in encephalitis lethargica—namely, "the study of recorded results gives a definite impression that the formula of cerebro-spinal fluid in encephalitis lethargica is normal or nearly so."

On July 1st a hypodermic injection of one million pure influenza virus was given; seven days later, when a second dose, the first, was administered, improvement began. Brudzinski's sign being less pronounced, the temperature fell, and the patient was discharged on July 14th.

antigen was given; seven days later, when a second dose, the same in amount as the first, was administered, improvement was noted. Four more injections followed on July 14th, 18th, 23rd, and 28th, the dosage on these occasions being 1, 1 1/2, 2, and 3 million respectively. Improvement was steadily maintained. On July 18th Kernig's sign and Brudzinski's sign had disappeared, while the child was taking its food well and putting on flesh. On July 23rd little headache remained. After the last injection, on July 28th the discs were normal. After the last injection convalescence proceeded with great rapidity and the patient was able to walk in the garden on August 2nd, and about a fortnight later was in possession of her usual health and activity.

INGUINAL HERNIA IN AN  
DAYS OLD.

during t

JOHN R. KEITH, M.D.

STRANGULATED INGUINAL HERNIA IN AN  
INFANT SIXTEEN DAYS OLD.

Driffield, E. Yorks

**STRANGULATED INGUINAL HERNIA IN AN INFANT SIXTEEN DAYS OLD.**

Actual strangulation of an inguinal hernia during the first few weeks of life appears to be sufficiently infrequent to warrant the following record. Somewhat similar cases were reported by Dr. Simmons in the JOURNAL of July 24th, 1924, and by Miss Herzfeld in that of October 11th, 1924.

This infant, born prematurely in the seventh month, was operated on for inguinal hernia. This was kept reduced until the age of sixteen days, when it came out at 1 a.m. on the sixteenth day, and was found to be irreducible and strangulated.

The infant, born prematurely in the seventh month, was reported by Dr. Simmons as being healthy at birth, August 24th, 1924, and by Miss Herzfeld in that city on September 1924.

This infant, eight months old, did not act satisfactorily, and died at 11 a.m., on the sixteenth day of October, 1924, while, and soon after, the mother was nursing him naturally.

noticed to have a right inguinal hernia at 11 a.m. on the day without difficulty, but the bowels did not act. The infant was treated by the breast feeds were not well taken. At 11 a.m. on the day after birth the hernia was found to be irreducible, and postural treatment was applied, but without success.

At 4 p.m. the same day I was asked to operation. The infant, which weighed only 5 lb., and the pulse 130. In the right groin the temperature was 99° and the size of a pigeon's egg. There was a tense cystic swelling. Gentle attempts at reduction were unsuccessful. No testicle could be felt in the scrotum on this side. In view of the danger of very light chloroform anaesthesia was undertaken by Dr. Wilfrid Milligan of Ansell. Before operate at once. The induction of normal saline was injected the incision was made 40 c.cm of dark blood-stained fluid, and about subcutaneously a quantity of dark blood-stained fluid, and there to contain a small intestine, black and covered here and the bowel five inches of lymph. The obstruction was relieved, and the bowel flushed repeatedly with hot saline lotion. As soon as the bowel showed a slight inclination to revive it was returned to the abdominal cavity. The sac, which was of the funicular type, was ligated and one catgut suture passed through the external femoral ring.

The child was put back to the mother's breast, and apart from some restlessness and stained motion on the following day was the advanced

The baby was put back to the mother's breast, and apart from the passage of a blood-stained motion on the following day the recovery was without incident.

The interesting feature about the case was the advanced degree of strangulation—actually bordering upon gangrene—which had occurred so soon after impaction. The case also illustrates the urgent necessity for operation immediately palliative methods have failed.

## Reviews.

### ORTHOPAEDIC SURGERY.

As far as our knowledge goes—we write under correction—the book on *Orthopaedic Surgery*,<sup>1</sup> by Mr. W. A. COCHRANE, assistant surgeon to the Royal Infirmary, Edinburgh, is the first modern handbook on the subject published in Scotland. We welcome it for this reason and also on its merits.

The first eighty-five pages deal with an aspect of orthopaedics to which little attention has hitherto been given in this country, yet the pathological results of faulty posture have been much insisted upon by a certain school of surgeons in America. Many symptoms, such as constipation and other "medical" conditions, are attributed to visceroptosis, which it is asserted is itself the result of faulty posture. On this side of the Atlantic we are inclined to regard such faults of posture as lordosis and kyphosis as the effects and not the causes of disease. Much further study will be necessary before the truth can be ascertained. In the meantime, good must come from the bringing forward of this subject in Mr. Cochrane's treatise. His experience as a clinical assistant at the Massachusetts General Hospital at Boston, U.S.A., has qualified him as an exponent of the practice of the Boston school of orthopaedics.

The second part of the book, which includes all but the first eighty-five pages, is arranged on a regional basis, beginning with the foot. The anatomy and statics of each part are adequately and clearly stated, and methods of treatment and of preparing and applying plaster-of-Paris and such appliances as foot-plates are clearly described. When he comes to treat of the pelvis and hip-joint Mr. Cochrane adopts the American view of the frequency and importance of such lesions as strain and malformation or displacement of the parts entering into or situated near the sacro-iliac joint. This, again, is a view that might be more seriously considered in this country. It seems possible that some of the bonesetters' triumphs may be achieved in cases of this sort which have been overlooked by surgeons. In reference to what is somewhat oddly called "painful back-ache," the importance of anatomical variations from normal in the lower part of the spinal column is insisted upon, and various abnormalities are illustrated by means of x-ray pictures. The radical treatment of such deep-seated conditions is, of course, difficult. A great deal of attention has been paid in New England to the question of back strain, which, whether acute or chronic, seems to afflict the American male much more often than the British. Spinal supports are not in much favour with British orthopaedic surgeons, but under the name of back-braces of various kinds they are advocated by the school of Goldthwait, and no doubt are often of use. Certainly they are pleasanter to the wearer than the plaster jackets which are also described and advised for certain cases in this book. The relation of round shoulders—"stoop-shoulder deformity," as the author and the Americans prefer to call it—with abnormalities of the scapula is an interesting subject, but one which is not illuminated by much dead-house pathology, opportunities of dissecting such cases being necessarily rare. Here again Goldthwait has insisted on the importance and frequency of such aberrations from normal. It is good that the views of a distinguished authority, which have hitherto not been much considered here, should be stated fairly, and we are obliged to Mr. Cochrane for doing so. For the rest the usual subjects of orthopaedic textbooks are lucidly dealt with in a manner which should be useful to practitioners. The illustrations are numerous and clear, and answer their purpose well.

### NEURITIS AND NEURALGIA.

On the subject of this book, *Neuritis and Neuralgia*,<sup>2</sup> Dr. WILFRED HARRIS can write as an accepted authority, and he has succeeded in giving us a work which is full

<sup>1</sup> *Orthopaedic Surgery*. By W. A. Cochrane, M.B., Ch.B., F.R.C.S.E. Edinburgh: E. and S. Livingstone. 1925. (Demy 8vo, pp. xxiii + 528; 504 figures. 21s. net, postage 8s.)

<sup>2</sup> *Neuritis and Neuralgia*. By Wilfred Harris, M.D. (Cantab.), F.R.C.P. (Lond.). Oxford Medical Publications. London: Humphrey Milford, Oxford University Press. 1925. (Demy 8vo, pp. xiv + 418; 45 figures. 12s. 6d. net.)

of interest and information. It is no disadvantage that the text is coloured by a strong personal note, for any possible drawback on this account is amply made up by the extensive experience upon which the author draws—an experience which is freely used to enrich his clinical descriptions.

Multiple neuritis forms the subject of one chapter; in it the usual types of the disease receive adequate recognition and description, and its value is enhanced by the discussion of rare forms which have come under the author's own observation, such as that associated with haematoporphyria. The various forms of neuritis which affect the cerebro-spinal nerves and nerve plexuses are carefully described, with numerous useful clinical notes. The diagnosis and treatment of sciatica are well discussed, and the different lesions of the cranial nerves receive adequate notice in lucid and concise chapters. But the chapters which are most likely to attract the attention of the reader are those dealing with the fifth cranial nerve, the gustatory functions, and the various types of trigeminal neuralgia. In writing of the last the author can draw upon an unusually ripe experience; he has provided a remarkably full and valuable account of the nature and treatment of paroxysmal trigeminal neuralgia, in which full details of his own method of alcohol injection are given. Such rare conditions as glosso-pharyngeal neuralgia and geniculate neuralgia are very fully described, and in these, as in other matters, the anatomical and physiological descriptions lend an additional value. There is a chapter on migraine and allied neuralgias, which provides again many illuminating cases from the author's experience. The illustrations, both figures and photographs, are good; at the price of 12s. 6d. we think that the volume is a very valuable and informing production.

### UROLOGY.

THAT the American School of Urology is in a flourishing condition is shown by the excellent literature it has produced during the last ten years, and the latest work coming from this source, *Young's Practice of Urology*,<sup>3</sup> is yet another proof that genito-urinary surgery has fully established itself as a definite specialty on the other side of the Atlantic. Dr. H. H. Young, with whom is associated Dr. DAVID M. DAVIS in the production of these two volumes, is, of course, already well known in urological literature, and much of the contents of this book has already appeared in urological periodicals. It is, however, undoubtedly an advantage that these important contributions to the subject of urology have been gathered together. The author is particularly well known as the champion of perineal prostatectomy, and his operative results are given here. That in his hands the perineal route has justified itself would seem to be proved up to the hilt, since in seven years during the last twenty the annual mortality has worked out at zero. Even when the hospital type of patient is considered the mortality rate is remarkably low, there being 36 deaths in 1,049 consecutive cases operated on in hospital, giving a mortality of 3.4 per cent. This is considerably lower than any figure that can be furnished on this side of the Atlantic for suprapubic prostatectomy. It is also interesting to note that, contrary to what has been the experience of most British urologists, Young has found that his mortality rate definitely increases with each decade of life, so that after 75 years of age the operation is considerably more dangerous. The most frequent cause of death would appear to have been pneumonia, renal failure being second on the list. This, again, is contrary to the experience of most other surgeons, in whose mortality tables these two items appear in the reverse order. From this we are forced to conclude that the tests of renal function and preliminary treatment of the patient are remarkably successful in Dr. Young's clinic. Another chapter worthy of particular attention is that on urogenital infections, and infestations. The author and his collaborators have been carrying out at the Brady Urological Institute since 1917 a systematic search for better germicides and

<sup>3</sup> *Young's Practice of Urology*. By Hugh H. Young and David M. Davis, with the collaboration of Franklin P. Johnson. Philadelphia and London: W. B. Saunders Company, Ltd. 1925. (Sup. roy. 8vo; Vol. I, pp. 746; 482 figures, 17 plates. Vol. II, pp. iii + 738; 521 figures, 3 plates. £5 5s. net the two volumes.)

antiseptics, and in this chapter is given a summary of their results. Numerous drugs have been tested for stability, germicidal strength, toxicity, and reliability. Amongst the preparations used intravenously have been mercurochrome, gentian violet, crystal violet, acriflavine, and proflavine. Good results would appear to have been obtained from all of these preparations, but after reading this chapter and other articles that have already appeared in urological journals, the average surgeon will hesitate to take the risk that these intravenous injections would appear to entail. However, we agree with Dr. Young, and also with that great authority Erlich, that the future hope of improvement in the treatment of many infections of the urinary tract lies in chemotherapeutics and in the discovery of an efficient disinfectant that can be administered intravenously without risk to the patient. Whatever criticisms might be directed against the author's work on this important branch of urology, no one can fail to admire the thoroughness with which the investigations at the Brady Institute are being conducted. The most important feature of the chapter on tuberculosis is an attempt to justify the radical methods adopted by the author in genital tuberculosis.

The second volume deals with less controversial matter and ends in four chapters on: "Urology in infancy and childhood," "Urology and urologists in the war," "Testicular and prostatic organotherapy," and "The study and teaching of urology." The chapter on organotherapy has been contributed by Dr. D. S. Macht, whose work on the internal secretion of the prostate is well known on this side of the Atlantic.

We must not conclude this review of Dr. Young's book without referring to the excellent illustrations and coloured plates with which it is provided. Like the majority of American medical publications, a certain lavishness has been shown in this respect, but although the numerous illustrations must add materially to the cost of production and the price of the book, they undoubtedly assist the reader. In conclusion, it may be said that, although many will disagree with the opinions expressed by the author in dealing with some of the more controversial points in genito-urinary surgery, no one can rise from the perusal of these volumes without a feeling of admiration for the thoroughness and skill with which they have been prepared. Young's *Practice of Urology* will take its place with Cabot's *Modern Urology* as one of the two most important American works on genito-urinary surgery.

#### DYSTROPHIES AND DIARRHOEAS OF INFANCY.

PROFESSOR LANGSTEIN has written a short book on dystrophies and diarrhoeas in infancy,<sup>4</sup> and in it he has included all the chronic nutritional disorders, a subject which has produced a cloud of theories which have only served to darken knowledge. Dr. Langstein's aim in writing his book, which he says is the fruit of fifteen years' clinical experience, is to simplify both the clinical pathology and the treatment of these conditions. As to classification and nomenclature, he is not satisfied with the scheme of Czerny and Keller based on etiology and comprising the three factors of food, infection, and constitution, nor with that of Finkelstein based on clinical features, and divided into disturbance of balance, dyspepsia, decomposition, and intoxication. He falls back upon a simple clinical division into the group dystrophy where wasting is the predominant feature, and the group diarrhoea where that is the chief symptom. In this simple classification he follows the recent trend of opinion both in Germany and America, and he justifies the caution and conservatism of the British school which has always hesitated to accept the theoretical and very complicated views of the subject which have been put forward in Germany. Fortunately his aim at simplification does not stop at classification, but extends to treatment. He ridicules the employment of complicated food formulae and of numerous varieties of milk foods. Either for the healthy or the sick infant he finds a complete system of dietetics in two simple dilutions of

milk (with the addition of sugar), in buttermilk, or in human milk.

The book falls naturally into the two broad clinical divisions he has chosen, and in each he deals in an orderly way with pathogenesis and causation, with the clinical features and their degrees of severity, and with treatment. An important and valuable feature is the inclusion of a considerable number of typical cases, which are illustrated by very complete clinical charts showing the essential data in a graphic form, and also by excellent photographs of the babies before and after treatment. These case records and photographs make the book more accessible to those who have difficulty in reading the German language. Further, the book is also unusual in an introduction which describes the healthy or *eutrophic* baby, again with good photographs, and thus furnishes the essential foundation of physiology. It is a noteworthy contribution to a difficult subject, especially in bringing clearness and simplicity where before there has been much complication and obscurity; and also in giving a sufficient number of case records by means of which the views and the results of the author may be examined and tested.

#### AN OPHTHALMIC BIRTHDAY PRESENT.

EDWARD JACKSON is the doyen of ophthalmic surgeons in the United States of America, and in honour of his seventieth birthday some three hundred American ophthalmic surgeons have presented him, as a token of their appreciation of his distinguished and unselfish services to ophthalmology, with a volume of contributions to the literature of that subject. It bears the title *Contributions to Ophthalmic Science*,<sup>5</sup> and has been edited by Drs. William H. Crisp and William C. Finnoff. Dr. G. E. de Schweinitz introduces the scientific papers by a sketch of the life and work of Dr. Jackson. He is a native of Pennsylvania, and after gaining some experience elsewhere became professor of ophthalmology in Philadelphia. Some years later he went to Denver, and became professor in the University of Colorado. He has been a great teacher and a prolific writer. At the end of the volume is a bibliography of his contributions to ophthalmology and general medicine, which fills fifteen pages of closely printed titles; the first is a single paper in 1882 on mydriatics, and each succeeding year the number increases until in 1925 the titles fill nearly a quarto page. He wrote books also, and edited the *American Journal of Ophthalmology*. He possesses a trained mathematical mind, and is deeply versed in physiological optics; so that he was able to apply theory to the elucidation of the practice of retinoscopy and muscle balance when these were mysteries. Withal he is intensely practical, as witness his lecture (the Jacob Lambert Lecture) on "The prevention of blindness by good lighting."

To review so many as forty communications which form the subject-matter of this tribute would be impracticable. Perhaps those which make the strongest appeal are the following: "Studies in ocular fatigue," by Conrad Berens, L. H. Hardy, and H. F. Pierce is a fascinating piece of research. "The general management of incipient cataract in adult life," by Luther C. Peter, may well be studied by all ophthalmic surgeons. The author is convinced that improvement in vision, where there are only the earliest signs of striae, can be obtained by subconjunctival cyanide injections followed by the instillation of Dor's solution; well formed opaque striae cannot be absorbed by this method. "The cataract operation of election," by L. Webster Fox, is suggestive; he has tried all forms of operation, and after much experience concludes that the method of the linear extraction with iridectomy and capsulotomy is the best and safest.

But there are many other papers of interest, and very many fine illustrations. The book is worthy of its dedication to the veteran ophthalmologist. Dr. Edward Jackson must be proud to have elicited such a tribute from his friends.

<sup>4</sup> *Dystrophien und Durchfallskrankheiten im Säuglingsalter*. Wegweiser für den Praktischen Arzt von Dr. Leo Langstein. Leipzig: G. Thieme. 1926. (Roy. 8vo, pp. 207; 73 figures, 70 charts. M.14; bound, M.16.)

<sup>5</sup> *Contributions to Ophthalmic Science*. Dedicated to Dr. Edward Jackson by his pupils and colleagues in the United States. Menasha, Wisconsin: George Banta Publishing Company. 1925. (Sup. roy. 8vo, pp. xiv + 519; illustrated.)

## "ANNALS OF MEDICAL HISTORY."

THE summer number of the *Annals of Medical History*<sup>6</sup> opens with an article by Dr. Theodore H. Bast on the life and time of Adolf Kussmaul (1822-1902), whose impressive portrait appears on the cover, and whose death-bed is reproduced as the frontispiece. His name, signifying "kissing mouth," was thought to be a handicap to professional success, but he declined any change, and declared that he was descended from the great Oribasius, and, indeed, used this name for some of his privately published poems. In his article on medical numismatics Dr. Fielding H. Garrison deals in a charmingly learned manner with medals, medical coins, plaques, jetons, touch-pieces, and tokens, and pays a tribute to the skill of Professor Tait Mackenzie. To those intending to become surgeons Dr. J. H. Gibbon holds up the example of Samuel D. Gross, who was a prodigious writer, and by what he published did much to make American surgery respected abroad. In his account of pioneer medicine in Western Pennsylvania Dr. Theodore Diller shows how many of the medical men in the eighteenth century were also military officers, and provides some fine portraits. Dr. W. B. Howell's article "Concerning some old medical journals" is inspired by a study of the first volume of the *Lancet*, the centenary of which was celebrated in 1923. Dr. Joseph Walsh, in a well illustrated article, gives a short history of the career, with five portraits, of Galen, and describes his discovery of the function of the recurrent laryngeal nerve. The two remaining articles deal with Chinese medicine; K. K. Chen and S. H. Ling supply interesting accounts of the great surgeon Hua Tu (115-205 A.D.), who, by rendering patients unconscious by means of an anaesthetic mixture, was able to do laparotomies and even end-to-end anastomoses; and of Pen Tsao, who doubled the number of drugs in use. Dr. Wang Chi Min of Hangchow describes China's contributions to medicine in the four periods of the ancient or legendary times, the historical or classical, the mediaeval or controversial, and the modern or transitional.

## NOTES ON BOOKS.

PROTOZOÖLOGY is one of the branches of science which have progressed so rapidly in recent years that their devotees are in danger of having general principles obscured by details. Professor CALKINS, who has recently published a well written and well illustrated book entitled *The Biology of the Protozoa*,<sup>7</sup> considers that, although many advances have been made in taxonomy, morphology, cytology, physiology, pathology, and so on, there is "no common aim, little common background, and no common point of view through which these many aspects of protozoa study are woven together in any definite way to make a science of protozoology." His book is accordingly an attempt of one of the best known American teachers of the subject to provide this unifying background and common point of view; in it he discusses the general structure, physiology, reproduction and fertilization, and vitality of the protozoa, and the special morphology and taxonomy of the four great groups of the phylum—the Mastigophora, Sarcodina, Infusoria, and Sporozoa. Many keys are given, and many succinct definitions provided. The whole of protozoology is surveyed—not merely the parasitic forms—and so the book is one primarily for the zoologist. The medical biologist, however, will learn much from its perusal, and will gain that sense of perspective which is so necessary for a complete understanding. The tendency to specialize in the parasitic forms only, at the expense of the more natural free-living types, leads to many misunderstandings and misinterpretations, and can only be corrected by the wider knowledge supplied by more general works such as this.

VOLUME VII<sup>8</sup> of the archives published by the School of Tropical Medicine at Lisbon will doubtless be useful as a work of reference, but does not contain much of interest for the practitioner. Of the four contributions in it the first, which fills more than four hundred pages, gives an account of the

climate of Portuguese India, with a wealth of detail as to the physical geography, geology, and vegetation, and of the temperature, humidity, and other meteorological observations made in various regions and districts. These are carefully tabulated, and may be valuable therefore from a statistical point of view, but it seems that a good deal of unnecessary information is included—for example, the degree of mist month by month since 1860. The compilation must have been a labour of love, for to the general reader it is about as interesting as Bradshaw—a work which it in some respects resembles. The second article is a report on the prophylaxis of paludism in the Portuguese colonies, which was presented at the International Malaria Congress at Rome. This consists of general remarks, acquiring added interest from the quaintness of the expressions, being apparently a verbatim translation of Portuguese into English. The third is a contribution to the history of malaria in Portugal, and is divided into three parts. The first deals with the disease prior to the fifteenth century, the second with the period from the fifteenth to the seventeenth, and the last brings the subject down to the early years of the second half of the nineteenth century. In the final section is given a summary, in the form of minutes drawn up by Professor Kopke, of the proceedings of the International Congress on Sleeping Sickness.

Dr. CAROLINE W. LATIMER has revised her book entitled *Girl and Woman*,<sup>9</sup> the first edition of which we reviewed on April 9th, 1910 (p. 878). The book is written in simple language, and has a popular appeal, inasmuch as it discusses the physical, mental, and moral disturbances of girlhood, the daily life during school-days and after, personal hygiene, and such special subjects as cardiac disability in youth, the inheritance of insanity, and instruction on matters of health and sex.

Dr. J. J. SCANLAN has reprinted in a small book, under the title *Medico-Legal Factors in Accident Insurance*,<sup>10</sup> three of his contributions to medical newspapers. He advocates the adoption under the Workmen's Compensation Acts of a schedule of fixed amounts of compensation for specific injuries. At the same time, he seems to admit that it is very difficult to set up a percentage scale of incapacity, though the Ministry of Pensions assesses various injuries in terms of money for gratuities or in terms of percentage incapacity for life pensions. The second article presents some medico-legal aspects of general practice; and in the third the art of medical assessing is discussed. Dr. Scanlan's style is disjointed, and his aim is not always clear. His merits are brevity and occasional appropriateness in illustration.

<sup>6</sup> *Girl and Woman*. By Caroline Wormley Latimer, M.D., M.A. With an Introduction by Howard A. Kelly, M.D. New edition. New York and London: D. Appleton and Co. 1926. (Cr. 8vo, pp. xviii + 331. 7s. 6d. net.)  
<sup>7</sup> *Medico-Legal Factors in Accident Insurance*. By J. J. Scanlan, L.R.C.S. and F.R.C.P. London: Post Magazine, 9, St. Andrew Street, E.C.4. 1926. (Cr. 8vo, pp. 27. 1s. net; post free, 1s. 2d.)

## PREPARATIONS AND APPLIANCES.

## Gland-holding Forceps.

Dr. WILLIAM ANDERSON (assistant surgeon, Aberdeen Royal Infirmary) writes: In removing cascating tuberculous glands it is frequently difficult to obtain a firm hold by the ordinary gland-holding forceps, and artery forceps tend to tear the capsule, thereby soiling the wound. The forceps here illustrated, designed

by Mr. L. G. Walters, medical student, Aberdeen University, and made by Messrs. Down Brothers, Ltd., London, has proved to be very helpful for this purpose. It consists of two cups, which on application grip the gland, and by further closing of the handles the gland is transfixed by a pin on which the upper cup moves. As the cups are closely applied to the gland, leakage of the contents is prevented, and a very satisfactory hold is obtained by the transfixing pin.

## A Sight Exerciser for Children.

Dr. Kenneth R. Smith, formerly of the R.A.F. Medical Service, has designed a simple apparatus for exercising the sight of children. He was led to its construction by the success of sight-training in the treatment of heterophoria in the Royal Air Force. Accepting Worth's observation that the vision of infants is monocular, and that binocular vision develops gradually in the first six years of life,

<sup>8</sup> *Annals of Medical History*. Vol. III, No. 2, June, 1926. Edited by Francis R. Packard, M.D. New York: Paul B. Hoeber, Inc.; London: Baillière Tindall and Cox. 1926. (8½ x 12½, pp. 95-211; illustrated. Subscription in Great Britain £2 2s. per volume of four numbers.)  
<sup>9</sup> *The Biology of the Protozoa*. By Gary N. Calkins, Ph.D. London: Baillière, Tindall and Cox. 1926. (Med. 8vo, pp. ix + 233; 238 figures. 35s. net.)  
<sup>10</sup> *Arquivos de Higiene e Patologia Eritéica*. Vol. VII. Lisbon: Pap. e Tip. Casa Portuguesa. 1925. (Med. 8vo, pp. 556; illustrated.)

Dr. Smith concluded that the development might be assisted and squint discouraged by an apparatus which would compel the child to use both eyes. A child's picture book, or an elementary lesson-book, or a card of letters of the alphabet, is supported on an adjustable book-rest. To this book-rest is connected, by a hinged attachment, a wooden guiding rod, which can be moved up and down but not laterally. The guiding rod terminates in an eyepiece which is of one of two forms. One form is a blackened vertical fin, somewhat like the tail of an aeroplane, behind which a notch to rest on the bridge of the nose keeps portions of the fields of vision of the two eyes separate. The other form resembles the eyepiece of the stereoscope, but without prisms or lenses. When a child looks through either eyepiece, it is only by binocular vision that it can see the whole picture or the whole series of letters. Of three letters in a row, with the first eyepiece it will see the left-hand letter with the left eye, the right-hand letter with the right eye, and the middle letter with both eyes. With the second kind of eyepiece it sees the left-hand letter with the right eye, the right-hand letter with the left eye, and the central letter again with both. In this way, Dr. Smith says, the tendency of vision in one eye to inhibit vision in the other—a tendency which exists up to the end of the sixth year of age—is neutralized. The child's attention is compulsorily attracted to that part of the field of vision which is not visible to the other eye; and the difficulty of getting a child to see with the squinting eye is overcome. Errors of refraction should, of course, be corrected. The child may be given a pencil and a piece of paper and told to copy the letters or figures which he sees without looking at his hands. Children who can read should read aloud when using the exerciser. Children of 3 or 4 years of age, it is said, use the exerciser easily. The exercises should be stopped or varied when the child's attention begins to flag.

#### Measurement of Ultra-violet Radiation.

Messrs. H. D. Griffith, B.A., and John S. Taylor, M.B., Ch.B., have devised a cadmium photo-electric violet radiation intensity. To measure peptic purposes a material must be of light of the wave-length responsible. Cadmium exposed behind a quartz window fulfils this condition. Cadmium is completely insensitive to visible light of a wave-length greater than 350 mμ, while the quartz window cuts off all radiation of a wave-length less than 200 mμ. The maximum sensitivity is, approximately, at 300 mμ. The photo-electric cell is glass-walled and has a receptacle or side tube blown on to it. One end of the cell is closed by a quartz window. A microscopic cover-glass shields the inside of the quartz window, while a globule of cadmium introduced into the receptacle is distilled so as to cover part of the glass wall of the cell with a layer of the metal. When the highly evacuated cell has been prepared the cadmium globule and the cover-glass fall down into the side tube, and the cell is filled with inert gas at low pressure. A plate inside the cell serves as the photo-electric electrode, and the rate of loss of charge is measured by an electro-scope. The time between charge and discharge is proportional to the intensity of the ultra-violet radiation falling on the cell. The apparatus is made by Watson and Sons, Ltd., 43, Parker Street, Kingsway, London, W.C.2.

## THE STATE OF THE PUBLIC HEALTH.

### SIR GEORGE NEWMAN'S REPORT FOR 1925.

#### ENGLAND AND WALES.

#### [Second Notice.\*]

#### GENERAL EPIDEMIOLOGY.

ENTERIC FEVER (including paratyphoid) was less prevalent, 2,779 cases being reported in 1925, as against 4,121 in 1924, 3,211 in 1923, and 2,414 in 1922. There was an increased incidence of both scarlet fever and diphtheria; in the first case the notifications numbered 91,362 in 1925, as compared with 84,654 in the previous year; while diphtheria notifications rose from 40,009 in 1923 and 41,980 in 1924 to 47,720 in 1925. The diphtheria death rate continues to fall. In 1911, of every 1,000 persons attacked 104 died, whereas in 1925 the death rate was only 58. This reduction is attributed partly to decline in the severity of the disease and partly to improved methods of diagnosis and treatment. As in the previous report, reference is made to the prevention of diphtheria by immunization. In the preparation of the immunizing mixture toxin has now been replaced by toxoid, which is toxin treated by formalin so as to become non-toxic while retaining immunizing powers. A toxoid-antitoxin mixture is at present being extensively employed; it has proved to be effective and free from any danger of loss of potency or dissociation of the antitoxin constituent. In the early part of the year, as the result of a survey by the Ministry, it was found that 4,528 children and adults had been treated by the Schick method in fourteen different schools. Most of those found positive were immunized, and

in every case the schools had been free from epidemic diphtheria. Only two mild cases had occurred in treated children, and six in Schick-negative children who had not been immunized. Sir George Newman states that a small percentage of children seem to be unable to develop and retain immunity, but in these any attack of diphtheria is slight. He expresses surprise that there are still many hospitals for infectious diseases in which nurses are allowed to attend diphtheria cases without having been offered the advantage of becoming protected by immunization. He adds that one large authority calculated that the total cost to the hospital of each nurse who contracted diphtheria was £28 10s., while the cost of immunizing a nurse was 2s. 9d. It has not yet been possible to ascertain how long the protection afforded by immunization lasts. Deaths due to influenza and pneumonia decreased, the respective figures being 12,721 and 36,990 in 1925, as compared with 18,995 and 38,970 in the previous year. Sir George Newman considers that at present the medical prophylaxis of influenza is unreliable, vaccines, throat gargling, and nasal douching having been found unsatisfactory.

#### Measles.

The number of deaths attributed to measles and rubella in 1925 was 5,379. Sir George Newman explains that since there is at present no effective means of preventing or controlling either of these maladies, compulsory general notification would be of little value. In areas where the essential point in treatment—good nursing—is available in the homes or provided by the local authority, the Ministry welcomes the adoption of notification. A short account is given of the attempts made to discover the cause of measles since Francis Home in 1759 tried, with doubtful success, to cause experimental infection in man, nor were those who followed him in this line of research—Wachsel (circa 1809), Speranza (1822), Katona (1842), McGirr (1850-51), and Bufalini (1869)—more fortunate, though Hektoen in 1905 seems to have produced a mild form of disease. It is doubtful also whether it can be conveyed to animals, though an atypical form has been produced. The conclusions at present are that uncomplicated measles is a mild and non-fatal disease, due to a non-filterable virus which has not yet been isolated, but which is present during the first thirty hours of the eruption in the buccal and nasal secretions, and also in the blood of patients. The gravity and high mortality of measles seem to be due to the associated streptococcal, pneumococcal, and influenzal infections. The serum of convalescent patients has been believed to have a prophylactic value in some cases, but the immunity is apparently very transient (two to three months, according to Zingher), and the supply of such serum is too limited to permit its employment on a large scale in epidemic periods. Degwitz has reported the preparation of a prophylactic serum from sheep, and it is stated that the Ministry, in conjunction with the Medical Research Council, is watching his investigations closely.

#### Encephalitis Lethargica.

In 1925 notifications were received of 2,635 cases of encephalitis lethargica with 1,372 deaths, as compared with 5,039 cases with 1,467 deaths in 1924, and 1,025 cases with 531 deaths in 1923. It is believed that, though these figures do not reflect accurately the true case incidence of the disease, yet that each year the number of cases wrongly diagnosed as being encephalitis lethargica is decreasing, and that an increasing number of mild or atypical cases is being included in the returns. The figures of the seven years during which it has been notifiable gave an average death rate for the period of 51.2 per cent., and suggest that a larger proportion of those attacked are ultimately killed by it than is indicated by the current records of hospitals or particular local epidemics. The disease appears to be more prevalent during the second quarter of the year. The proportion of patients who sustain some permanent injury of the mind or body remains high. Provision has been made recently by the Metropolitan Asylum Board for the special treatment of such cases, and hope is expressed that further accommodation of this kind will come into existence throughout the country.

\* First notice, BRITISH MEDICAL JOURNAL, September 11th, p. 431.

*Cancer.*

In the course of the last thirty-five years the cancer mortality has doubled, and during the past five years, with the exception of 1922, there has been an annual increase of the death rate amounting to 30 to 40 per million of the population. Sir George Newman agrees that part of this increase is due to improvements in diagnosis and recording the causes of death, and also to a larger proportion of persons surviving till the "cancer age," but he believes that there is also an appreciable increase of the disease. It is held to-day that cancer is due either to a specific exogenous infection or to some permanent change in the cell nutrition or metabolism. After referring to the researches of Peyton Rous, and of Gye and Barnard, it is added that such observations only constitute one stage in the vast field of research necessary before an effective preventive weapon can be forged. An outline is given of the activities of the Departmental Committee on Cancer, the British Empire Cancer Campaign, and other organizations, and the need of statistical investigation and public education being undertaken more extensively by local health authorities is emphasized.

*Tuberculosis.*

The prominent position still held by tuberculosis as a problem of public health is shown by thirty-one pages of the report being devoted to this disease. Notification and the examination of doubtful cases are generally receiving increasing attention, but examples are given of some areas which are still remiss in these respects. In a general review of the tuberculosis position in which reference is made to his previous survey in 1920, Sir George Newman indicates five great influences in operation. Increased attention to sanitary reform, factory legislation, child welfare, and predisposing diseases coincides with an advance in the social and communal health since 1851. There has been a general spread of knowledge about the contagiousness of the disease, especially since 1881; special measures of prevention and treatment have been employed, and there has been an increase in the immunization and resistance of the population as a whole. Looking forward, he emphasizes the importance of educational work, and mentions in this respect the new Public Health Act (1925), which gives increased powers to local authorities to provide public lectures and demonstrations. He considers that the community generally needs at present to learn the vital importance of seeking skilled advice as soon as there is the slightest suspicion of the lungs being affected, and of accepting treatment as soon as recommended, instead of waiting until the disease has sapped the working capacity; the treatment should be continued as long as ordered, and not be interrupted by a return to work as soon as the obvious signs have disappeared. Sir George Newman then gives an account of the tuberculosis medical service, including in it general practitioners, school and tuberculosis medical officers, medical superintendents of the various residential institutions, and medical officers of health. A table is given to show the nature of the controlling authorities of the 474 hospitals and sanatoriums approved by the Minister of Health for the treatment of tuberculosis, with over 21,000 beds. Local authorities have the charge of 428 dispensaries and voluntary organizations of 55. Considerable importance is attached to occupational treatment, and a report on special vocational training centres appears as an addendum to this section. The difficulties of this work are frankly admitted, and it is recognized that patients so trained can, as a rule, be employed subsequently only by an *ad hoc* organization. The last of the training centres for tuberculous ex-service men carried on in co-operation with the Ministry of Pensions closed in April, 1925. Through these centres 1,252 men had passed, of whom 996 were resident in England. The extent of success was diminished by too many patients having been received with extensive or active disease for lasting benefit to be gained. Of the 996 patients 612 completed the course of training satisfactorily, 134 failed for medical reasons, and 250 for non-medical causes. The after-history of 574 of the 612 fully trained patients is available, and it is

shown that 25 per cent. were incapacitated within twenty months. From the industrial point of view it appears that only 7 per cent. of the 996 men have materially benefited, in spite of receiving treatment allowances during training, pensions subsequently, and in many cases money grants for tools and equipment; it is therefore concluded that the extension of a scheme of this kind to the civilian population would be inadvisable.

*MATERNITY AND CHILD WELFARE.*

Work under the Maternity and Child Welfare Act (1918), being permissive and not statutory, varies considerably in different districts, and financial considerations have also an important bearing on such questions as the extension of established schemes or the inauguration of new ones. The maternal mortality rate has increased from 3.70 to 3.86 per 1,000 births. Ante-natal work is in progress at 675 centres, but it is still the case that skilled supervision of pregnancy is neither requested nor received by the great majority of women, and so there is at present little hope of a substantial reduction in the maternal death rate, or in the amount of injury and disability so frequently associated with child-bearing. The hope is expressed that greater use will be made of ante-natal clinics established as part of maternity and child welfare schemes, and associated with maternity institutions for consultation and treatment. Attention is also directed to the importance of recognizing venereal disease in the course of maternity and child welfare work. There are now 146 institutions in England recognized by the Ministry for maternity work, and containing 2,216 beds. Reports from 116 recognized maternity homes, excluding voluntary hospitals, show that during the year under review 21,559 women were admitted for confinement or observation; 17,459 were delivered by midwives, and 3,930 by medical practitioners. There were 46 cases of notified puerperal fever in these homes with 14 deaths, and 96 maternal deaths occurred from other causes. In view of the expense attached to the upkeep of a maternity home and the preference of many women for confinement in their own homes, it is recommended that more attention should be given to domiciliary midwifery, and assistance be provided by local authorities in necessitous cases in respect of payment for the midwife's services, contingent upon there having been ante-natal supervision by the midwife or at a maternity centre. Local authorities have previously been invited to consider the provision of sterilized dressings, pads, and towels, but it appears that there has been little response except in Birmingham and Blackburn. During the puerperium also skilled nursing is very necessary.

Recognized infant welfare centres number 2,195, of which 561 are controlled by county councils, 861 by local sanitary authorities, and 773 by voluntary organizations. Establishments for the orthopaedic treatment of children have been approved in 17 county areas, 11 county boroughs, and 15 other areas, while in other parts of the country arrangements have been made for treatment at orthopaedic hospitals. It is urged that there should be no artificial demarcation, so far as treatment is concerned, between the child of pre-school age and the child at school. Increasing attention is now being directed to the mental health of the child, especially with a view to build up adequate self-reliance, independence, and emotional control; it is recognized that the mental health of adults is largely determined by influences operative in early childhood. Sir George Newman states, however, that in maternity and child welfare work such psychological considerations still receive too scanty recognition, and that few, if any, local authorities have considered the possibility of the practical application of psychology in this connexion. He thinks that the child's mental health should be no less a matter of national concern than its physical health, and believes that there is evidence that the principles governing the preservation of mental health can be given practical expression. He adds that the early signs of mental ill health in children can be recognized and their causes traced and treated. Parents can be enlightened on these matters by instruction and propaganda.

(To be concluded.)

## NOVA ET VETERA.

### FRACASTORIUS.

THE readers of Dr. Paul de Kruif's witty book *Microbe Hunters* will find there many and happy illustrations of the extreme futility of both discussion as to "priority" in scientific research and the award of championships. Was Koch a greater man than Pasteur? is as idle a question as, Was Shakespeare a greater poet than Aeschylus? One might indeed go much further and maintain that in scientific investigation, the emotional element, the appeal, not to cold reason, but to the dramatic instincts of mankind, has had much more to do in the making of scientific history than we like to admit.

The place in history of Hieronymus Fracastoro illustrates this. Fracastoro has secured an immortality of the same kind as that of Brook Taylor. Very few educated men have never heard of "Taylor's theorem," but even of those who could correctly enunciate that theorem, only a small minority know anything more of the defunct Taylor than that it was his theorem. Probably even more people have heard, or rather read, the name of Fracastoro, since that sinful curiosity upon which Samuel Johnson commented must have led millions to turn up in a dictionary the word "syphilis," where they have found that "the word is borrowed from the name of a figure in Fracastoro's poem, *Syphilidis Libri III.*" That little spar, one word of a Latin poem, has saved the physician of the Tridentine Council from the waters of oblivion.

Fracastoro's poem was published in 1530, when he was 47 years of age; he lived another twenty-three years and was a voluminous writer. But, with one exception, no work of his other than the poem has been reprinted for more than a century. The exception is a treatise on *Contagion and Contagious Diseases*, which was first published in 1546. Of this book two versions have been issued within our generation. In 1893 Dr. Léon Meunier of Paris brought out a translation into French (with a reprint of the Latin text), and in 1910 an abridged German translation, by Professor Viktor Fossel, was issued in the series of *Klassiker der Medizin* edited by Professor Karl Sudhoff. Fracastoro's Latin prose has no special grace, so that nothing is lost by reading a translation. It is, however, better to study him in Meunier's edition because Fossel's interpretation of the phrase "trifling abbreviations" (*geringfügige Kürzungen*) is rather generous, and all might not agree with him as what really are "interpolations of altogether unessential matters."

The historical importance of the book is this: that Fracastoro was the first writer to state with precision the biological doctrine of contagion. He first postulated a living *contagium* capable of propagation. Fracastoro was not of course the first to perceive that diseases spread from person to person; that had been recognized much more than a thousand years before his day; nor did he even accept the logical conclusion of his own reasoning. Thus, although he is satisfied that syphilis is usually spread by contagion, he shrinks from accepting that as a universal explanation, for "it would have been impossible that the contagion, which in itself is a slow business and not readily conceived, should have spread in so short a time over so great an area." Yet the logical distinction between Fracastoro's doctrine and the traditional doctrine is clear. In none of the ancient writers is there a hint that they conceived of contagion as more than the passing on from person to person of an unchanged something; there was no question of an active part played by the recipient of contagion—he was a mere conducting medium. Fracastoro had a clearer insight. He likened contagion in disease to the rotting of fruits in contact.

The process was, he thought, analogous to a putrefaction. Hampered as we all must be by the common associations of words, he was troubled by the associations of the word he used, *putrefactio*, but he was striving to express the idea of fermentation, and actually used the illustration of the souring of wine. What happened, he said, was that *seminaria*<sup>1</sup> were conveyed from one person to another, and these germs, "which possess the property of propagating and begetting their like," are the essential factors of contagious disease. Hence the essential difference between poisoning and contagion. The poison can destroy but it cannot initiate a putrefaction—that is, a fermentation. The differences between diseases conveyed by direct contact, by fomites and through the air, are referred to differences in structure and viability of the germs. In the sixth chapter of his first book, Fracastoro definitely contrasts the biological and the metaphysical standpoints. The thesis is that "The cause of contagions taking effect *ad distans* is not to be referred to occult properties."

"Those who invoke occult properties," he writes, "extricate themselves easily from these difficulties, all they have to do is to explain the whole of such contagions by reference to these properties, so that here and in other matters, they can rest quite happily and free from any trouble." He then proceeds to show how idle are these metaphysical speculations. Nothing which is a "spiritual quality" will help us to explain the facts that in contagions "not only is there a putrefaction but from the original germs others are begotten and propagated similar to the first in nature and quality (*natura et missione*)."

Such was the teaching of Fracastoro in 1546, and, making the necessary allowance for differences of vocabulary and the occasional use of illustrations which are fictitious, there is hardly anything in his exposition which could not be taught to medical students in 1926. Shall we, then, say that not to Pasteur and Koch but to Fracastoro belongs the credit of the germ theory of disease, and that we have ignorantly given to men of our own time that which rightfully belongs to our ancestors? If we endeavour to move the "previous question" and assert that Fracastoro only guessed what Pasteur proved, the *laudator temporis acti*, particularly if he has read Dr. de Kruif's book, will most assuredly retort that Pasteur frequently reached correct and enormously important conclusions by processes which the modern statistician, logician, and bacteriologist, who agree on so few topics, would agree in regarding as hopelessly insufficient. The right answer to the question is, we believe, this: there is no such thing as an absolute scale of values in scientific truth. We must judge everything pragmatically. Fracastoro may have been, perhaps was, as great a genius as Pasteur, but the world actually owes little to Fracastoro and much to Pasteur, for the seed Fracastoro sowed fell upon stony ground and that sowed by Pasteur upon good ground.

It is perhaps true that many of the most important of the results which we attribute to the application of the experimental method might have been deduced by strict reasoning from natural observation. But it is a matter of historical fact that until the experiment (very often a quite inconclusive experiment) has been made, the logical deduction fails to convince. Thousands of able physicians in the days before experiment must have read Fracastoro; to none of them did his argument seem really important. This was not his fault nor their fault. There may be truths of the greatest importance to us in Chinese literature, but until they are translated into a language we can understand they are of no value to us, and it seems as if, at least in medicine, the language of experiment is the only one all can understand and appreciate even when it is ungrammatical. Still, the image of the old physician of Verona deserves a niche in the medical Pantheon. His claim to immortality ought not to depend upon the coining of one word.

<sup>1</sup> According to Lewis and Short, *seminarium* is not used in classical Latin in any other sense than that of a seed-plot or nursery, but Fracastoro evidently means something more nearly equivalent to *semen*, and the French and German translators rightly render by *germe* and *Keim*.

SATURDAY, SEPTEMBER 18TH, 1926.

## THE REGISTRATION OF NURSING HOMES.

LONG before the days of Caesar Augustus there went forth decrees for the registration of the people, but there has never before this era been a time when registrations were so numerous. Some yearn for registration, others have registration thrust upon them. Some aver that registration gives the registered a monopoly inimical to the body politic; others, like the circus proprietors, declare that it has killed their job and robbed the children of a thing of joy. A year or two ago the nurses, or most of them, clamoured for registration, and got it; now they desire that the "homes" and institutions where they work should also be registered. The project has been the subject of inquiry by a Select Committee of the House of Commons. The report of this committee has been published,<sup>1</sup> and the substance of it has appeared in our columns.<sup>2</sup> The evidence given to the committee was reported in our parliamentary column from time to time. Some of it was rather wild, or founded on hearsay, but the report itself contains a sufficiency of facts and some reasoned arguments; the balance of opinion is discovered to be in support of the recommendations made. The committee seems always to have held in mind the vision of the intensely human, and humane, purpose of nursing homes, and to have striven to frame its recommendations in such fashion as to help them in their work and not to harry them. That attitude is to be counted to it for righteousness.

The first business of the committee was to discover whether there was any case for registration. The answer given is an unhesitating affirmative. We must take their word for that. The members of the committee, after hearing the available evidence, conclude: "The need for the registration and supervision in nursing homes is fully established." We may wonder at the diversity of the evidence. The witnesses of the Ministry of Health and the British Medical Association, on the one hand, stated that there was no evidence of widespread abuses; but the College of Nursing and the Society of Medical Officers of Health made out a strong case to the contrary, the latter stating that "privately managed nursing homes form the source of constant complaints to medical officers of health all over the country." A strong point made in favour of the committee's recommendation is the fact that there is no essential difference between the maternity home and the nursing home, and since the former is registered by Act of Parliament the other should be also. The decision to supervise being taken, there arose the question by what body and what type of visitor this should be done. The committee considers that the authority should neither be so central as to be removed from contact with local conditions, nor so parochial as to involve risk of personal interest in the homes. These considerations

caused it to recommend the county councils and county borough councils, with the London County Council in the metropolis. The recommendation seems to be wise.

Evidence given by the British Medical Association indicated that there was no objection to registration provided that doctors and nurses were on the local committees upon which the work was to devolve; that medical records and case-sheets were not to be open to inspection; and that doctors who received patients into their homes for treatment should be exempt from registration, or at any rate inspection. The committee endorsed the first and second suggestions, but disagreed with the third, although it had some sympathy for it. It formed the opinion that "if an individual doctor decides for purposes of gain habitually to take in patients, whether into his private house or into a nursing home, he does so with the full knowledge that he is taking up a definite trade and entering into competition with other persons who have to comply with such regulations as may be enforced." In these circumstances the committee declined to recommend any general exemption from registration of inspection in respect of any premises covered by the definition of a nursing home on the sole ground that such premises were under the direct control of a medical practitioner, resident or otherwise. "From this it would follow," the committee continued, "that the present practice of exempting maternity homes in such cases should no longer be permitted." The committee, however, made other recommendations which relieve the doctor of much of the anxiety that was expressed in the discussions at the Representative Meetings of the Association, for the committee is opposed to the compulsory exhibition of brass plates and printed rules, or any methods of inspection that would destroy privacy or a home-like atmosphere.

So much for the report. What may we conceive will be the effect of legislation in accordance with its recommendations? It would seem certain that two consequences will ensue: private nursing homes will be fewer, and with a higher tariff on the average; and private wards and private hospitals will increase. Another probable effect of registration and supervision of nursing homes will be that their standard will be raised—that, indeed, is the aim of the proposed legislation. The raising of the standard involves an increase of costs. Many small homes may be expected to go out of business, because they will not be able to meet the capital charges for improvements nor the increased current expenditure on trained staff. So that a provision which has for some years in some fashion met the needs of many middle-class patients will almost certainly be diminished, if it does not cease altogether. There will be nothing for these patients between the high-class nursing homes the cost of which they cannot pay, and the hospital charity, except in those few places where foresight and public spirit have provided wards and rooms for private patients in the voluntary hospital, or in private hospitals.

It therefore behoves the boards of the voluntary hospitals to be up and doing whilst it is yet day. They should recognize the new conditions; and at the very least have ready to hand a considered scheme for the extension of the work of the hospital for which they are responsible to meet the needs of private patients. Such a scheme they could put into operation when it became necessary owing to the contemplated changes, or earlier should a demand for it develop among the great middle-class public.

## A GOOD HEALTHY WATER.

LAST year we commented on Sir Alexander Houston's hope that some day the Thames would become again a salmon river. In his report for the year ending March, 1926,<sup>1</sup>—his twentieth as Director of Water Examination to the Metropolitan Water Board—a large proportion of the pages is devoted to the romance of the New River. The more prosaic portions of the report deal with the chlorination of Thames and New River water; with filters and pre-filtration waters; with meteorological notes, suspended solids, and a variety of health subjects. Sir Alexander Houston wonders if the Londoner realizes what chlorination means bacteriologically and financially. By its use, under skilled supervision continually exercised, the water of London is kept pure even in flood periods, while the addition of ammonium chloride and potassium permanganate, as "taste preventers" with some sterilizing action, renders the water palatable. There was a slight breakdown in "taste prevention" in the Palmers Green area in December last; but the weather condition (cold fog, with decrease in organic matter) had already provided a warning that less of the chemicals was necessary, and the reduction had been made just before the first complaints reached the Water Board. From the financial point of view heavy capital expenditure for larger storage accommodation and increased filter beds is avoided by chlorination, and filtration can be carried on more rapidly.

The examination of pre-filtration waters is based on the view that if these waters can be pronounced epidemiologically "safe," the perfect working of the filtration process becomes almost of secondary importance except for the production of a physically attractive fluid. Sir Alexander Houston regards the condition of pre-filtration waters as the pulse of the water supply that must be felt. Experiments in filtration have been conducted at the Barn Elm (West Middlesex) works since January, 1923. It has been found that the life and activity of filters can be materially increased by a preliminary rapid filtration of most of the growths and much of the suspended matters in water. Preliminary filters, working at the exceedingly high rate of at least 120 gallons per square foot per hour, can remove so much of the materials which choke slow sand filters that the latter can work five times as fast and enjoy a longer life. It is hoped that this double process of filtration will prove in the end more economical than the older single process. Sir Alexander Houston has no objection to the water being less perfect physically and chemically provided it is as safe, or safer, bacteriologically and epidemiologically. He looks to chlorination for this safety. In some places, however, it would appear that any economy effected by rapid filtration would be neutralized by increase in the costs of pumping. Experiments are therefore being conducted in the inhibition of the development of algal and other growths in water by the addition of minute doses of copper sulphate. The author notes that in looking through his album of photographs of organisms present in water he has been struck by the countless occasions on which the water should have tasted fishy (*Eudorina*, *Pandorina*, *Uroglena*, etc.); like ripe cucumbers (*Synura*); grassy (*Aphanizomenon*, etc.); and aromatic (*Asterionella*, *Tabellaria*, etc.). He recalls only one or two instances in which London water had really an unpleasant taste due to growths; one, which many readers will remember, in 1913, when the West Middlesex water was variously described as tasting like geraniums,

rotten fish, and castor oil. The taste was due to a copious growth of *Tabellaria* and *Asterionella*; the dissemination was caused by some raking operations carried out to prolong the life of the filter beds between successive cleanings; the taste was removed by adding two or three pounds of permanganate per million gallons of water; and it is gratifying to learn that the raking operations have been discontinued.

A new and fascinating, but perplexing, problem has arisen in water biology; and a section of the report is devoted to leptospira in London water. The subject was dealt with by Dr. Hindle in the BRITISH MEDICAL JOURNAL of July 11th, 1925 (p. 57). Sir Alexander Houston, on the available evidence, does not regard the presence of leptospira as of paramount significance, whether on scientific or common-sense grounds. Leptospira are found to be almost universally present, not only in the raw sources of supply, but also in filtered waters and in pure deep wells. All cultures have proved to be non-pathogenic, except the cultures from one well, the supply from which has now been chlorinated; and it is satisfactory to know that leptospira are easily killed by minimal doses of chlorine. At the same time, as Sir Alexander Houston says, the possibility of a change from a saprophyte to a pathogen opens many disquieting possibilities. He thinks that rats have something to do with poisoning water and slime, and rendering possible the production of jaundice by leptospiral water. At all events, he cannot believe that infection comes simply from saprophytic leptospira occurring in water, soil, or foodstuffs. On such a hypothesis the whole world would be jaundiced.

Sir Alexander Houston is a picturesque, discursive, and at times inconsequent compiler of reports, and we turn with interest to the earlier part of his report, the "Romance of the New River," which he describes as an oasis in a desert of dry facts, but it is really half a continent. Therein he displays his imagination, and with a touch, as he says, of *joie de vivre*, describes some of the wonderful and romantic happenings of bygone days. For him there has been nothing in the annals of preventive medicine finer than Sir Hugh Myddelton's conception of three hundred years ago, which led to the safeguarding of the health of the metropolis by bringing pure water from the Chadwell and Amwell springs in Hertfordshire by an artificial channel forty miles long to London. And so, after a preliminary account of the history of the undertaking of the thirty-six "adventurers" and King James I, we are led by Sir Alexander Houston along the whole course of the New River, from its origin in the upper River Lee and Amwell Pond to its termination in New River Head at the Metropolitan Water Board offices in Clerkenwell. The journey is illustrated by sketch maps and innumerable photographs, some of beauty spots or monuments of interest, such as Rye House, sundry churches, and Temple Bar, others of pumping stations. For the power and utility of the latter Sir Alexander Houston has no less admiration than for the beauty of the former; for are they not all part of "an immortal work: since men cannot more nearly imitate the Deity than in bestowing health"? The author's enthusiasm will inspire many of his readers to make the pilgrimage themselves—if only they possessed that master key which opens to him the private property through which the New River runs.

Sir Alexander Houston's adventurous fancy leads him beyond the waters of the New River. He does not confine his interest in meteorology to mere

<sup>1</sup> London: P. S. King and Son, Ltd. Price, 21s

rainfall. He enters on a diatribe against London fogs, asserts the possibly controvertible principle that "everyone has the right not only to live, but to enjoy life to the full"; and looks forward to the time when everybody will indulge in ultra-violet rays or sun-baths, with or without suitable permeable clothing. He discusses the opinions of Sir James Berry, who, in a lecture to the Hunterian Society last January, ventured to dispute the "lack of iodine" theory of goitre. Finally, Sir Alexander Houston describes how, by means of copper sulphate and chlorine, the water of swimming-baths can be kept sweet and clean-looking for a prolonged period with hardly any changes of water and no complaints as regards taste and smell. He admits, however, that the use of the same water over prolonged periods, even if well purified, is sentimentally objectionable. It would seem that the saving effected by the Metropolitan Water Board by its methods of chlorination and rapid filtration fully justifies the expense of issuing this delightful report of its Director of Water Examination.

#### THE WASSERMANN AND THE FLOCCULATION REACTIONS.

An attempt to add to the present scanty information about the nature of the essential mechanism underlying the Wassermann and flocculation reactions has been made in the Bacteriological Department of the University of Edinburgh by Professor T. J. Mackie and Dr. H. Ferguson Watson, who have set themselves to solve the question whether these syphilitic serum reactions represent the activity of a natural antibody present normally in all serums in minimal amounts, and capable of being reinforced by certain infections, or whether they are the result of metabolic alteration or chemical changes in the tissues incidental to syphilis and the other conditions in which the Wassermann reaction has been noted. The occurrence of similar reactions with the serums of various normal adult animals, including the rabbit, ox, sheep, horse, mouse, cat, dog, macacus, and pig, was also investigated. Although attention was paid more particularly to the complement fixation phenomena, the flocculation reaction was studied simultaneously. A uniform antigen and technique were used throughout, and the process of fractioning positive and negative human and animal serums by carbon dioxide was utilized as an aid in the analysis of the serum function. The two investigators submit an interpretation of the Wassermann reaction, which is set out in detail in the *Journal of Hygiene* (July 14th, 1926). In the rabbit, ox, sheep, and horse the serum heated to 55° C. was found to retain the power of fixing complement in conjunction with the antigen used in the Wassermann test, and to produce a flocculation effect similar to that of syphilitic serum. They believe that these reactions represent a natural property of the serum, and do not depend upon pathological conditions, though they are absent in man, guinea-pigs, frogs, and white rats. The unheated serum of the white rat, however, was found to yield a definite, though weakly positive, flocculation reaction, while in some other animals there was dissociation in the reactions. Thus in the pig, pigeon, fowl, and cat a negative Wassermann reaction was associated with a positive flocculation, while the reverse was the case of the dog, mouse, and rabbit. In the mouse the positive Wassermann reaction was uniformly weak, and in the other normal animals it was always limited in degree, contrasting sharply with the pronounced reaction characteristic of active syphilis in man. Moreover, it was shown that young animals, 3 to 8 weeks old, of species giving positive reactions, reacted negatively. In rabbits the reacting power increased progressively with age, and in parallel with the development of

a natural antibody. This parallelism supported the view that these reactions were due to principles in the serum resembling antibodies. The deduction made is that the serum reactions in the case of syphilis are due to such principles, which resemble antibodies and are homologous to antibodies natural to certain species and widely distributed among animals. Marked augmentation of the Wassermann reaction in rabbits was produced experimentally by immunization with heterophile antigen, confirming the work of Taniguchi, and by infection with *B. tuberculosis*. It was next found that the fractions of normal human serum insoluble in carbonic acid and the serum of negatively reacting animals might yield, after being heated at 55° C., a weak complement fixation effect with the Wassermann antigen. This property is described as being "masked" in whole serum, lost when heat over 60° C. is employed, and more marked in the unheated fraction. Differences were detected in this respect between the serum fractions of normal animals and of human syphilitics, but these are held to be due to variations in the total content of the reacting substances in the serum and their distribution in the serum fractions. These observations seem to indicate that the principle in serum responsible for the Wassermann reaction is present normally, in minimal amount and in a "masked" state, even in those animals which give a negative reaction when tested in the usual way. It would appear, therefore, that the diagnostic reaction in man is due to the non-specific augmentation of this natural principle. The dissociation of the Wassermann and flocculation properties in syphilitic serum was manifested by carbon dioxide fractioning, the soluble fraction being more active in the flocculation test, and the insoluble moiety in the Wassermann test, though in some cases the dissociation was less obvious and in others absent. It is suggested, therefore, that the Wassermann syphilis reaction represents the increase of a "lipoidophile" antibody naturally present in the serum in minimal amount, and in a masked state, which in syphilis is non-specifically augmented in an analogous manner to the augmentation of the natural anti-sheep haemolysin by heterologous stimuli.

#### THE MEANING OF PHYSIOLOGY.

THE discipline of physical science does not encourage in its servants excursions beyond the stubborn facts which feed its thought. Yet, if we have "intelletto d'amore," the imagination must often break the barrier between the objective contemplation of nature and the wider consciousness of man, though it may only tease the soul in secret. When, however, an eminent man of science does attempt an expression of the wider meaning of his observation of matter, our reticence will not forbid enjoyment of his philosophical adventures. In *Brain and Heart*<sup>1</sup> we have a translation of a series of lectures by Professor G. Fano, a distinguished Italian physiologist who, as Professor E. H. Starling in a foreword very properly observes, "is also philosopher, artist, and man of letters." Since the translation conveys to us a live picture of the manner of man we feel the author to be, it is probable that the translator, Dr. Helen Ingleby, has been very successful in her task. The lectures represent the autobiography of an experimentalist whose observations feed his restless mind. His problem is the investigation of the physical nature of the heart rhythm and the inwardness of the excitability of living matter. His material is the fresh-water tortoise, his apparatus the conventional equipment of the physiological laboratory artfully employed. Much productive work has derived

<sup>1</sup> *Brain and Heart. Lectures on Physiology. By Giulio Fano. Translated by Helen Ingleby. With a Foreword by Professor E. H. Starling. C.M.G., M.D., D.Sc., F.R.S. Oxford Medical Publications. London: H. Milford, Oxford University Press. 1926. (Demy 8vo, pp. ix + 142; 19 figures. 8s. 6d. net.)*

from the immediate conclusions of the author's experimental work in the special problems with which it has been concerned. But imagination generalizes his studies and, in his mind, the heart and brain become symbolic respectively of the automatism and the wilfulness of life—the inescapable logic of causation and the physical perversity of the mind. Man can comprehend the rhythm of the tides, but the wind bloweth where it listeth. Professor Fano seeks first a meaning for “living matter,” and finds in the reciprocity of structure and function the fundamental principle of life. With Cuvier, he sees form to be more significant than matter. The theory of evolution represents the intuitive faith of the human mind in the reasonableness of the conception of continuity rather than a deductively established dogma. Living matter is only material organized by the “will to live,” and the search for the origin of life becomes a subjective inquiry weighted by a temperamental bias respecting finality. And so there remains only purposive action as the characteristic of life, and the tortoise teaches the author that this resides in an inherent automatism of metabolism upon which is imposed an excitability which, paradoxically, is essentially directive inhibition of vital automatism. Enough has been said to indicate the scope of this little book. It is one to which the adjective “stimulating” may properly be applied, and it will not fail to raise contention; for, while some may find consolation in the assumption of a “cosmic will,” there will be others who will feel that there is no rest for the human spirit that resolutely pursues the continuity of Nature which passes unbroken still into the unknown.

#### INDUSTRIAL HYGIENE IN JAPAN.

THE expansion of the factory system in Japan has been attended by industrial legislation which has proved of benefit both to the industries concerned and to the employees engaged in them. The Japanese Factory Act came into effective operation in 1916, and year by year since that date hygienic standards in factories have shown improvement. An account of present-day conditions is contained in a recent report<sup>1</sup> by Dr. Yasutoshi Kose, inspector of factories and mines under the Home Department, Tokyo. There are, he states, 343 inspectors and assistant inspectors, of whom seven are physicians, for factories in Japan. The corresponding figures in the British Isles, excluding Ireland, were, in 1924, 205 inspectors and assistant inspectors, of whom five were physicians. The duties of the Japanese medical inspector include the supervision of safety in factories, the advancement of industrial hygiene, the prevention of industrial disease, and health propaganda generally among employers and workpeople. In these particulars his range of service is similar to that of a medical inspector in Great Britain. He has, however, additional functions in connexion with compensation for accidents. In the United Kingdom workmen's compensation, though under the Home Office, is not in charge of its Factory Department. Dr. Kose reports that of a total of some 20,000 factories in Japan, 52 per cent. are textile. In Great Britain in 1924, out of a total of 142,494 factories, less than 6 per cent. were textile. Of the total factory hands in Japan 60 per cent. are women; while of textile workers 81 per cent. are women. Of those female workers few are from the locality and few married. Most are girls brought in to the factories from agricultural districts and lodged in boarding-houses provided by employers. The boarding-houses at the large factories are usually of good type. Their equipment, heating, and ventilation are satisfactory, and their water supply abundant; the bathing accommodation, as in most Japanese dwellings, is a salient feature; the workers take a bath

every day or every other day, or at least twice in the week. This frequency, as Dr. Kose remarks, is different from other countries, among which it is to be feared Britain must be numbered, though Dr. Kose does not say so. Many factories have separate houses for the married workmen. The married miner lives, as a rule, in a tenement of from one to three rooms forming part of a common building. The quality of the food supplied in the boarding-houses comes under the scrutiny of the inspectors. For men the calories allowed are from 2,500 to 2,800 a day; for women from 2,300 to 2,500. All factories in Japan except the smallest have their own doctor. Large factories and most mines have their own hospital also, well equipped and staffed by competent medical men. The factory doctors, besides treating the sick and injured, advise employers in matters of hygiene, acting for this purpose in co-operation with, or under the guidance of, the medical inspectors of the Home Department. Accurate statistics of industrial mortality are not available, but steps are being taken to procure authoritative figures, which it is intended to publish. Existing data for 1925 show 11 cases of all forms of tuberculosis per 1,000 workers, 8 being cases of phthisis. The incidence of beri-beri was at the rate of 55 per 1,000, and that of trachoma at 19. Information on industrial sickness is incomplete, but reference is made to twenty-two cases of lead poisoning among storage battery workers, and also to the occurrence of poisoning by carbonic oxide and aniline. Among persons handling native wool and hair for use by upholsterers anthrax has been unknown for some years, but several cases come under notice annually in the bone manure trade, the raw material of which is imported from other countries. Ankylostomiasis is common in the collieries, and preventive measures are urgently required. Dr. Kose's report furnishes interesting information with regard to the industrial hygiene of Japan, revealing as it does the nature of the problems which call for attention and the methods adopted, or intended to be adopted, for their solution.

#### THE GOVERNMENT LABORATORY.

THE routine work of analytical chemistry must, we think, be a depressing pursuit. At all events, the report of the Government chemist for the year ending March, 1926,<sup>1</sup> is singularly unenlivening reading. One almost sighs for a report such as a mediaeval alchemist would have produced from the depths of his imagination. Sir Robert Robertson, with a stern sense of duty and a recognition of the need for economy, condenses his report on 445,606 investigations of samples into thirty-three pages. No amount of ingenuity, we believe, could extract an atom of amusement out of the report. Yet with eighteen Government departments pouring into his laboratory all sorts of material, from offal tobacco to sea water, from condensed milk and herb beer to sheep-dip and policeman's clothing, we feel sure that Sir Robert Robertson's staff must occasionally meet with some humorous incident. The number of samples examined was some 2,500 fewer than in the previous year, but still many thousand above the number for 1923-24. The Custom House has curtailed its efforts by more than 10,000 samples. The samples of wine and of tea have decreased; but the depression in tobacco samples, caused by the cessation of large exports to the Irish Free State, is gradually being made good. The silk duties have provided the Government chemist with some extra work. From the food examinations carried out for the Ministry of Agriculture it may be gathered that the producer is behaving himself very well on the whole; but we are not informed whether drainage from roads treated with the eleven samples of proprietary road dressings which were examined had any effect on the health of the fish in

<sup>1</sup> *Japan Medical World*, February, 1926.

<sup>1</sup> H.M. Stationery Office, 1s. 6d. net.

contiguous rivers. At one point the report drifts away from bald statement of examination results to note that proceedings against the sellers of the Sussex ground oats and of barley meal containing tapioca resulted in conviction of the sellers; though why they did, or why the sellers of sharps containing rice husks escaped, we are not told. The establishment of the Irish Free State has rendered it necessary to sample consignments of beer from that country. This, we gather, is not for the purpose of ensuring that the Guinness absorbed in Britain is of the right potency and flavour, but in order that the Government may get the full duty. One hundred and fifty-nine samples of matches were examined, but no white phosphorus was found. Of parcel post packages coming into this country 2,200 samples were sent to the laboratory; but the report does not tell us how many of these contained dutiable perfumery, essential oils, and so on. The Public Record Office submitted to the laboratory a silk tassel from a sixteenth-century seal which had become brittle, but the Government chemist could only report that there was no clear evidence of destruction by organisms. However, washings sent from the cleaning of the Leighton frescoes at the Victoria and Albert Museum showed that none of the original pigment was removed in the treatment, so that these works of art will no doubt be preserved for us. Amongst the papers communicated by members of the laboratory staff, the only one of medical interest concerned deposits of arsenic and copper on eating apples.

#### CARE OF THE DEAF.

For some fifteen years there has been a small society working in the interests of the deaf. Recently it has been reorganized under the title of "The National Institute for the Deaf." The president of the new society is Lord Charnwood, a man who has made his mark for judgement in other spheres. Besides a good working executive committee there is a strong medical committee, which combines practising aurists, school medical officers, and publicists. Deafness is a terrible affliction. The loss of hearing may not be so severe a handicap as the loss of sight, yet there can be little doubt that deafness causes more unhappiness than does blindness. Perhaps this is because our sympathies are more attune to the plight of the blind than that of the deaf. It is so difficult to communicate with the deaf; with the blind it is easy. Much has been done for the deaf in this country, but there is much more to be done before these sufferers get their fair chance in life. Under the Education Acts there are schools for the deaf up to the age of 16 years; they give splendid aid in training the youthful deaf, and in many cases following them up afterwards. But for the most part, after the age of 16 the main dependence must be upon voluntary societies. There are some sixty of these in the country, and if they were adequately supported much could be done for the youthful deaf and for those whose deafness is of later years. No less than 600 deaf and partly deaf leave the schools each year; and, excluding the partially hearing, there are some 40,000 deaf-born persons in the country. It is clear, therefore, that there is room for organization of the work of directing the deaf into suitable spheres of work. There are, besides, records of some 4,500 deaf in the workhouses and a couple of thousand in mental hospitals. The major part of these cases are due to old age, but there are some able-bodied amongst them for whom work should be found. The committee of the new institute, which has its offices at 67, Frith Street, Soho Square, London, W.1, has set itself two initial tasks: the first is to compile a list of trusts and charities for the deaf; by this research it has already discovered an almost unknown trust with an income of nearly £1,000 a year. The second, and more important,

task is an inquiry into the industrial conditions of the deaf in four or five distinctive areas. Such an inquiry will show in what branches of work the deaf most easily succeed; and in this way much economy of effort may be obtained in educational direction. The name "National Institute for the Deaf" is a reminder of the older National Institute for the Blind, and if the new institute for the deaf should attain a success such as has attended the labour of that for the blind, the organizers of the new society will deserve well of the community. But to achieve success there must be funds; the appeal is made for £2,000 a year for the carrying through of the initial investigations cited above; at present only £650 a year is assured.

#### MEMORANDUMS ON CANCER.

In August, 1923, the Ministry of Health issued for the guidance of local authorities a short general memorandum on cancer (Circular 426); summarizing in non-technical terms our knowledge regarding etiology and incidence, and offering suggestions for the guidance of public opinion. This was followed in March, 1924, by a memorandum on the effects of radium and x rays upon normal and cancerous tissues (Circular 476). Further memorandums appeared in May and July of the same year, the one relating to cancer of the breast and the results of surgical operation for that condition (Circular 496), and the other reviewing the main lines which experimental cancer research had followed in recent years, and the broad conclusions, negative as well as positive, which seemed to be deducible (Circular 516). The responsibility for these pronouncements, of which notices appeared in the JOURNAL on their publication, was undertaken by the Departmental Committee on Cancer appointed by the Minister of Health, with Sir George Newman as chairman. A further memorandum on cancer of the breast is being issued this week.<sup>1</sup> This supplements the information already given by incorporating the additional and more exact data which the committee has since obtained. The statements in the memorandum of May, 1924, based mainly on an examination of the literature, have been put to the practical test of several following-up inquiries by a subcommittee of medical officers of health. These investigations have established the previous conclusions of the committee on a firmer basis of fact, and demonstrate that the results of early complete operation are even better, in terms of subsequent healthy life, than had been revealed by the literature. We hope to refer again in more detail to this brief but authoritative summary of the position in regard to cancer of the breast.

#### THE ROYAL SANITARY INSTITUTE.

To commemorate its recent Jubilee and London Congress, over which Mr. Neville Chamberlain presided; the Royal Sanitary Institute has issued a retrospect of its history, compiled by Dr. Louis C. Parkes, one of the vice-presidents. The historical portion of the book is very complete, beginning with the early efforts of Dr. Lory Marsh and the few members of the first committee who took the trouble to attend meetings; tracing the extraordinary progress made in the face of financial difficulties; recording the incorporation of the Parkes Museum with the institute in 1883; describing the institute as it is to-day; and reproducing photographs of many eminent men who aided in its promotion and objects. At the end of the volume are special articles recording the sanitary progress of the last fifty years from the medical, sanitary engineering, architectural, and other aspects. Professor Bostock Hill, chairman of the council of the institute, describes the

<sup>1</sup> Ministry of Health. Memorandum on Cancer of the Breast (Circular 716). 1926. London: H.M. Stationery Office. 1d. net.

medical aspect. Public administration is dealt with by Sir William J. Collins, one of the vice-presidents; and the Hon. Sir John Cockburn, Colonel C. H. Melville, and Fleet Surgeon W. E. Home write on the oversea dominions, military hygiene, and sanitary advance at sea. The rest of the book summarizes the multifarious activities of the institute, including congresses and conferences, lectures and examinations, and the publication of transactions and a journal. There are now about 5,000 members and associates of the institute, the work is extended to India and most of the dominions, and since the institute obtained its present premises at 90, Buckingham Palace Road, in 1909, a much larger space has been available for the Parkes Museum. For this museum, which is open without charge, the public may well be grateful to the Royal Sanitary Institute.

## LEAGUE OF NATIONS ASSEMBLY.

[FROM OUR CORRESPONDENT AT GENEVA.]

THE brilliant skies under which the League of Nations Assembly is meeting at Geneva do not tempt the delegates to shorten their discussions. Some of the meetings are held in the open air, in the gardens of the Secretariat, and these continue until the closure is moved by the coming of dusk. The political barometer, too, is high; although there is a depression centred over Spain, and another over South America, a large anticyclone has set in from Germany. The welcome of the German delegates was all that could be desired, and the acclamations which greeted M. Briand's speech of goodwill, in which he said that France and Germany had had enough of battle and must now turn to co-operation in peace, will be long remembered.

### *Opium and Dangerous Drugs.*

The question of opium and other dangerous drugs is occupying a large place in the committee business of the Assembly. At a meeting of the League Council, M. Unden, the Swedish representative, gave a report on the eighth session of the Advisory Committee, and spoke in serious terms of the magnitude of the illicit traffic. He urged all States to complete without delay their ratification of the Geneva Convention of 1925, although he had to admit that his own country had not yet done so, and that the only States members of the League which had so far forwarded their ratifications of the Convention were Great Britain, Australia, New Zealand, the Union of South Africa, and India.

Sir Austen Chamberlain spoke strongly in the Council on this subject, emphasizing the great importance which attached to the ratification of the Geneva Convention, particularly by those States which are members of the Council. He said that the work of the Advisory Committee at the present time was seriously impeded and largely at a standstill for want of this ratification. On the proposal of M. Scialoja, the representative of Italy, the Council instructed a communication to be sent to the various States emphasizing the importance of speedy ratification, and decided also to draw the attention of States to the importance of the regular receipt of information from them on the traffic in drugs, including the quantities seized by their authorities, and, in the case of countries producing coca, statistics relating to the export of this raw material and of crude cocaine. Special attention was drawn in the Council to the steps taken in Great Britain to prevent the maritime insurance of consignments of opium or drugs destined for illicit purposes, and the Council decided to urge other countries to take similar steps. It was decided also to bring to the notice of all governments and of the Universal Postal Union the evidence available as to the extensive use of the post by illicit traffickers in morphine and other drugs with the Far East.

The question of this traffic also came up in the Fifth Committee of the Assembly, where M. Veverka, delegate

for Czecho-Slovakia, stated that there was no doubt that the quantity of drugs manufactured was considerably in excess of medical and scientific requirements; but until the Geneva Convention of 1925 came into operation effective control of the international traffic would be extremely difficult. M. Parra-Perez, the delegate for Venezuela, declared the production of narcotics at the present time to be from ten to twenty times in excess of what was required by medicine and science. Viscount Cecil also spoke of the seriousness of the situation and the need for ratifying the Geneva Convention, and Sir B. Mullick, delegate for India, gave statistics to show how well the Indian Government is fulfilling its duties in the matter of control. He said that steps had been taken to introduce an absolute prohibition of exports within a term of ten years—that is, by 1935—and that internal distribution was being gradually restricted in spite of the difficulties proceeding from the ingrained habits of the people.

The discussion is continuing in this Committee, and the matter will be brought in due course before the Assembly.

### *Epidemiological Intelligence.*

Viscount Ishii, the representative of Japan on the League Council, reported to the Council on the work of the Health Committee. He said that the committee was not yet in a position to submit definite recommendations regarding the establishment of the proposed sanitary and epidemiological bureau on the West Coast of Africa, but an experiment is being undertaken by the inspector-general of the Algerian medical service in the shape of the collection and transmission of such epidemiological intelligence as is at present available in northern, western, and central Africa, and the results will be reported to the Health Committee at its session next month. Viscount Ishii also described the nature of the revision by the recent International Sanitary Conference in Paris of the international convention of 1912. The revised convention makes it incumbent on the signatory States to notify the International Office of Public Health in Paris of the appearance and progress of the more important epidemic diseases in their territories; in addition, information has to be given concerning the measures imposed on ships arriving from infected territory, the existence of rat-plague in ports, and the sanitary equipment of ports. The Japanese statesman spoke of the great utility of the work done by the epidemiological intelligence service of the League.

### *Intellectual Co-operation.*

A statement was made to the Council by M. Briand on the work of the Committee on Intellectual Co-operation. He said that Madame Curie had compiled a report on inter-university relations, especially with regard to the award of scholarships to young students intending to engage in disinterested scientific study and research after obtaining their university degrees. At Madame Curie's suggestion a meeting of experts is to be summoned to help in co-ordinating this effort and to promote a fairer allocation of these scholarships in different fields of scientific activity, both in the exact sciences and the humanities. As regards the important problem of liaison between universities, university professors, and students, the Committee on Intellectual Co-operation reported that valuable results had been achieved by a recent meeting of representatives of the International Association of University Students. Another development along the lines of intellectual co-operation is an international museums office, to be established during the autumn. Proposals are also shortly to be submitted on certain natural extensions of copyright, such as *droit en suite*, which entitles the author to share in the surplus value which his work may fetch at public sales, and the *droit en respect*, in virtue of which any deliberate alteration of the text of a work by any person other than its author is prohibited. A further proposal is to create an international office of meteorology, which is considered a matter of some urgency. The Council of the League passed a resolution noting with satisfaction that the influence of intellectual co-operation is continually growing in the different countries, both members and non-members of the society of nations.

## Union of South Africa.

[FROM OUR CORRESPONDENT IN CAPE TOWN.]

### THE LATE DR. A. REITH FRASER.

THE funeral of the late Dr. A. Reith Fraser [of whom an obituary notice was published in our issue of July 31st] took place on July 12th at Plumstead Cemetery, Capetown, in the presence of a large gathering of friends and colleagues. The burial service at the graveside was conducted by Bishop W. T. Gaul, who, in the course of a brief but eloquent address, referred to the baffling mysteries of this life, exemplified by the taking away from our midst of a life so full of promise. Here was one, he said, "who was engaged in scientific investigation the results of which might have been of inestimable benefit to mankind at large, yet it had pleased the Almighty to remove him while many others, living lives of apparently no value to the community, were left. The pall-bearers, chosen from among Dr. Fraser's personal friends, were Mr. T. Lindsay Sandes, F.R.C.S., Mr. Ph. A. Smuts, F.R.C.S.E., Mr. C. E. Jones-Phillipson, F.R.C.S.E., Dr. A. W. S. Sichel, Dr. W. P. Mulligan, Dr. R. Lance Impey, Dr. J. P. Duncan, and Dr. D. Herman Wessels. The Western Branch of the British Medical Association, of which Dr. Reith Fraser was so popular and efficient an honorary secretary, was represented by the President (Dr. D. H. Wessels), Vice-President (Mr. T. Lindsay Sandes), and many members. Among others present at the ceremony were: Dr. G. Watson Robertson, Government pathologist; Dr. F. C. Willmot, assistant medical officer of health for the Union; Dr. W. Darley Hartley, editor of the *South African Medical Record*; Dr. C. L. Leipoldt, editor of the *Medical Journal of South Africa*; Dr. W. P. Cooney, medical superintendent of the City Hospital; Dr. Hugh Smith, Dr. D. J. Wood, Dr. C. H. Krüger, Dr. H. M. Bosman, Dr. C. C. Carr, representing the Southern Peninsula Medical Society; Mr. W. A. M. Beard, representing the Royal Cape Golf Club; Mr. J. Bruce Cleghorn and Mr. Berrange, representing the Civil Service Club; and many others. The wreaths were numerous and beautiful, and at the conclusion of the interment the grave was one mass of flowers, testifying to the esteem and affection with which Dr. Fraser was regarded. Among the floral tributes was one from the President, Council, and members of the British Medical Association (Western Branch).

### THE HEALTH OF THE CITY OF CAPE TOWN.

The annual report of the medical officer of health for the City of Capetown (Dr. T. Shadick Higgins) for the twelve months ended June 30th, 1925, has just been published. The deaths registered numbered 3,945 (1,298 European, 2,646 coloured, and 1 of unknown race), which is equivalent to an uncorrected annual death rate of 9.27 per 1,000 for all classes (11.04 European and 30.36 non-European). Corrected for outward and inward transfers, the true European death rate is given as 10.15. The report states: "The European death rate (corrected for outward transfers) for the year is the lowest recorded since unification. There has been a steady improvement in the European death rate since 1913-14, but no such improvement has taken place in the non-European death rate. It has again to be recorded that for the year under review the non-European death rate (corrected for outward transfers) was three times as great as the European." The true European infant mortality rate, corrected for inward and outward transfers, was 70.91 per 1,000 births. The non-European rate, corrected for outward transfers only, was 173.95. These figures are the lowest on record with the exception of the year 1921-22. The marked disparity between the figures for European and non-European, both as regards the death rate and infant mortality rate, should be noted by those with little experience in health matters as affecting the coloured races. The births registered in Capetown for the year 1924-25 numbered 7,439 (2,538 European, 4,897 coloured, and 4 of unknown origin), corresponding to an uncorrected annual birth rate of 36.33 per 1,000 for all classes (21.58 European and 56.19 non-European). The true European birth rate, corrected for

outward and inward transfers, was 21.22. The report states: "It will be seen from these figures that in spite of their higher death rate the natural increase of the non-European section of the Capetown population exceeded that of the European section by more than one thousand." The number of male births per 1,000 female births was 1,041 amongst Europeans and 1,063 amongst non-Europeans, as compared with 1,142 and 1,065 for the previous year. The percentage of illegitimate to total births was 5.8 amongst Europeans and 24.1 amongst non-Europeans. The number of stillbirths corrected for outward transfers was 432 (73 European and 359 non-European).

### HOSPITAL BOARD REFORM.

A Draft Ordinance to amend the law relating to the constitution of the Cape Hospital Board is at present before the Provincial Council. Among the more important provisions are the reduction of the number of members of the board from thirty-six to eighteen, and the abolition of local committees of management. The board as at present constituted is, many consider, unwieldy, and there is little doubt that on account of its repeated procrastinations and unbusinesslike procedure from time to time it has almost entirely lost the confidence of the public. So unsatisfactory has the position become that a large section of the members of the Hospital Board itself, favouring a scheme of decentralization, are actively urging that the board should be abolished altogether, and the control of individual hospitals vested in local committees responsible directly to the Administrator. The Draft Ordinance, however, allows for a policy of centralization, but has applied the pruning knife very freely. Under its provisions the reduced board of eighteen members may appoint committees of three to assist in the management of institutions. At present local committees consist of fifteen members elected by the subscribers residing in an area. There are close upon 200 persons at the present time engaged in the administration of hospitals in the Cape peninsula, and their reduction to eighteen may seem unnecessarily drastic; however, the intention of the Administrator, it is stated, is to give a board so reduced an opportunity to make good before introducing amending legislation. The Draft Ordinance provides that of the eighteen members to constitute the Cape Hospital Board one-sixth shall be appointed by the administrator, one-sixth by the honorary visiting medical officers, one-third by the local authorities, and one-third by the registered contributors. Doubt exists as to whether the newly constituted board will be able to break away from the past and make a fresh start. At any rate, the general feeling seems to be in the direction of giving the Administrator's scheme a fair trial, although there are many who would prefer to see a board consisting of twenty-five members, with provision made for committees of five from its number to act as local committees of management.

### NEW HOSPITAL AT BEAUFORT WEST.

On June 23rd, 1926, the ceremony of laying the foundation stone of the new hospital at Beaufort West was performed by the Administrator of the Cape Province (Mr. A. P. J. Fourie) in the presence of a large gathering, including many visitors from the outlying districts. The occasion was a great one for the town, the day being proclaimed a public holiday. Mr. A. R. Truter, chairman of the local hospital board, in introducing Mr. Fourie, gave a brief account of the efforts which had resulted in the building of the hospital, in which provision is made for sixteen beds at an approximate cost of £10,000. The building, which is already well advanced, occupies an eminently suitable site, exceeding 7 morgen in extent, granted by the town council. Voluntary effort has raised already a sum of £3,000 towards the cost of equipment; this is due in large measure to the co-operation of the Women's Hospital Board of Aid. Before laying the stone the Administrator was presented with a silver trowel by Mrs. Peter Weeber, to whose constant devotion to the interests of the hospital he referred in eulogistic terms. In the course of a speech dealing with the problem of hospital administration Mr. Fourie said: "Whilst the sick poor must be catered for at the expense of those who are

blessed with worldly competence, we know that they also need provision for hospital treatment, especially in isolated towns. But those who can afford to pay for treatment must, of course, do so. Their fees must be part of the hospital revenue, and they ought to pay not less than their attention costs the hospital. This is bare justice to those who subscribe to hospital funds, which are intended to cover treatment of those who cannot pay, and not treatment of those who can. The effect of proper management in this respect will keep down the daily cost per patient, which I find in some places reaches an abnormally high figure. A hospital, to be successful, must be managed with all those business instincts which one applies to one's own affairs, for in no other way can it be successful and serve the purpose for which it is established." Following the ceremony the Administrator was entertained at a public luncheon, where his health was proposed by Mr. W. M. Luscombe, M.P.C.

#### PROFESSOR JOLLY.

During the bicentenary celebrations of the founding of its medical faculty the University of Edinburgh conferred the honorary degree of LL.D. on Professor W. A. T. Jolly, dean of the Faculty of Medicine of the University of Capetown. By so doing the University of Edinburgh has done the younger university a signal honour. It is a fitting reward for consistently good work, not only in the field of research, but also in the organization of medical teaching. Ever since his appointment to the chair of physiology in 1911 Professor Jolly has thrown himself heart and soul into the task of building up the medical faculty, and it is due in no small measure to his energy and enthusiasm that Professor Jolly, who graduated M.B., Ch.B. at the University of Edinburgh in 1906, was lecturer in experimental physiology under Professor Sir E. Sharpey-Schafer when appointed to the chair of physiology at Capetown in 1911. He acted as chairman of the Medical Committee of the South African College, and, on its incorporation with the University of Capetown, became dean of the Faculty of Medicine. Professor Jolly is a member of the Royal Society of South Africa, and is its honorary secretary. He is a past-president of the Cape of Good Hope (Western) Branch of the British Medical Association, and continues to take a close interest in all its affairs, being a member of council at the present time. Professor Jolly is a universal favourite both with colleagues and students, and the news of the honour awarded by his Alma Mater gave very real pleasure to a wide circle of friends and colleagues.

### Scotland.

#### JAMES MACKENZIE INSTITUTE FOR CLINICAL RESEARCH, ST. ANDREWS.

The syllabus of work for the winter session of 1926 at the James Mackenzie Institute for Clinical Research includes meetings on Tuesdays for medical discussions and clinical meetings on Fridays. The subjects dealt with on the Tuesday afternoons will be found in our Diary, published weekly in the SUPPLEMENT. On October 5th the introductory address will be given by the honorary director on the muscles of the heart, intestinal tract, iris, and ciliary body, the discussion being opened by Professor Waterston. The two following discussions will be introduced by the Regius Professors of Aberdeen (Physiology) and Cambridge (Medicine), who will deal with high blood pressure from the physiological and clinical aspects respectively. Professor John Shaw Dunn of Manchester will speak on October 26th about the disturbance of renal function in experimental nephritis, and on November 2nd Dr. R. Barclay Ness of Glasgow will discuss the difficulties in diagnosis and prognosis in chronic Bright's disease. The treatment of arteriosclerosis will be considered by the Regius Professor of Medicine at Aberdeen on November 9th, and Dr. Hector Cameron will describe some forms of acidosis in children on the following Tuesday. The three subsequent discussions will be introduced respectively by Professor Adam

Patrick on diabetic coma, Mr. A. E. Maylard on the bearing of high blood pressure, albuminuria, and glycosuria on surgical operations, and Professor G. Lovell Gulland on these three conditions as affecting life insurance. Professor Murray Lyon will describe methods of influencing the blood pressure, on December 14th, and the present series will be closed on the following Tuesday by Major Walter Elliot, Parliamentary Under Secretary for Health, who will consider clinical research in its relation to the public health services. The syllabus of this course may be obtained from the secretary at the Institute.

#### TREATMENT OF VENEREAL DISEASES IN SCOTLAND.

A reprint has been published in pamphlet form of the chapter dealing with venereal diseases in the Annual Report of the Scottish Board of Health for 1925; it may be obtained through booksellers or from H.M. Stationery Office, price 2d. net. In addition to a description of these diseases, their diagnosis, treatment, and possible sequelae, conveyed in simple language and intended to have a popular appeal, information is given about the working of the forty-five approved treatment centres in Scotland during last year, with a summary of returns of patients treated up to the end of May, 1925. The pamphlet is designed to impress upon the lay public the importance of early and continued treatment of venereal diseases, to assist the general practitioner in diagnosis and treatment, and to indicate when he should have recourse to the public services. It is stated that during the year under review 25,243 cases were treated, as compared with 23,153 in the previous year, the number of new cases having risen from 12,316 to 13,011. It is believed that there is a progressive decrease in the incidence of syphilis in Scotland; there is also evidence that the serious nature of venereal diseases is becoming increasingly recognized. The percentage of patients abandoning treatment before the completion of the first course was 26, and of those finishing the first course, but before tests to establish the absence of disease, 23. Propaganda work was carried on by some local authorities, but the bulk of it was performed by the Scottish Committee of the British Social Hygiene Council.

#### NEW EDINBURGH VENEREAL DISEASE CLINIC.

The Public Health Committee of the Edinburgh Corporation has opened a new Seamen's Dispensary at Leith. This is intended to provide extended facilities for the diagnosis and treatment of male patients suffering from venereal disease at the Port of Leith. The dispensary will be open daily from 9.30 to 1, and from 3 to 8.30 p.m., for routine treatment, and a medical officer will be in attendance during the forenoons of Tuesday, Wednesday, Thursday, and Saturday, as well as on Monday and Thursday evenings. Routine treatment will be continued as before at the chief centre in the Royal Infirmary of Edinburgh.

#### PUBLIC HEALTH BACTERIOLOGICAL EXAMINATIONS IN EDINBURGH.

The public health authority in Edinburgh has recently made a new arrangement with regard to routine bacteriological examinations, which have hitherto been carried out at the Usher Institute of the university. From October 1st, 1926, such routine examinations will be carried out in the general arrangements will be much the same as in the past, the work being undertaken by the staff of the bacteriological department under the direction of the professor of bacteriology. Specimens sent by post on and after September 30th should be addressed to Bacteriological Department, University New Buildings, Teviot Place, Edinburgh. Specimens delivered by hand between 9 a.m. and 5 p.m. should be handed in at No. 2 Laboratory of the bacteriological department. After 5 p.m. on week-days or 1 p.m. on Saturdays, as well as on Sundays, specimens should be left at the Warder's House, University New Buildings. The present system of supplying containers and reporting results, both in writing or where necessary by telephone, will be continued. In cases of urgency, when an immediate examination of a specimen is required after the usual laboratory hours, application may be made by

telephone, when one of the members of the department will make the necessary arrangements for carrying out the examination.

#### EDINBURGH ROYAL MATERNITY HOSPITAL.

A letter has been sent by the directors of the Edinburgh Royal Maternity and Simpson Memorial Hospital to the Edinburgh Town Council, making an appeal for financial aid to the institution. The letter points out that the working of the hospital for some years past has resulted in deficits which have had to be met by legacies and from a small reserve fund. In view of the very difficult time lying ahead, the directors state that they must appeal to the local authorities and child welfare centres of the districts from which many of the patients are drawn. They base this appeal chiefly on the fact that the hospital affords its benefits to a great number of poor women who cannot make payment of any kind; also on the fact that one of the chief functions of the hospital is to train nurses for taking up maternity service and child welfare positions all over the country.

## Ireland.

#### TUBERCULOSIS MORTALITY IN DUBLIN.

MORTALITY from tuberculosis has been reduced considerably in recent years in Dublin. Earlier diagnosis, better treatment, and greater care exercised by the patients to prevent infection have contributed to this condition. The very high death rate, however, is sufficient to impress the necessity for still greater effort to stamp out the scourge. Dr. A. Trimble, chief tuberculosis officer for Belfast, issued recently a report of the condition in that city (see *BRITISH MEDICAL JOURNAL*, September 11th, p. 499). This stated that the rate had decreased by 30 per cent. in the last ten years and 68 per cent. in the last forty years, but the number of sufferers is still very high. In Dublin the mortality in the past ten years from tuberculosis has shown a greater decrease, being almost 50 per cent., as the following table shows:

|      | All forms. | Pulmonary. |
|------|------------|------------|
| 1916 | 1,390      | 1,065      |
| 1917 | 1,371      | 1,058      |
| 1918 | 1,163      | 896        |
| 1919 | 999        | 738        |
| 1920 | 820        | 615        |
| 1921 | 749        | 583        |
| 1922 | 738        | 574        |
| 1923 | 666        | 507        |
| 1924 | 623        | 505        |
| 1925 | 664        | 515        |

There has been a steady decrease in the deaths, and in considering the figures it must be borne in mind the present scheme for the treatment of tuberculosis in the county borough of Dublin only commenced in 1913. At the Dublin Corporation Dispensary, West Charles Street, where, under the supervision of Dr. P. J. Murray, chief tuberculosis officer, much work is being done to check the disease among the poor, an *Irish Independent* representative was informed that the cases examined were 1,294 in 1925, and of these 539 suffered from pulmonary tuberculosis and 156 from surgical tuberculosis. The number of these cases occupying with family one, two, or three or more rooms was: one room, 746; two rooms, 319; three rooms or more, 229. This shows the effect of bad housing on the spread of the disease. Notifications of the disease showed between 1916 and 1923 a decrease, but in 1924 and 1925 there were sharp increases. The figures were:

|      |     |      |     |
|------|-----|------|-----|
| 1916 | 750 | 1921 | 527 |
| 1917 | 761 | 1922 | 511 |
| 1918 | 814 | 1923 | 505 |
| 1919 | 734 | 1924 | 701 |
| 1920 | 583 | 1925 | 690 |

No explanation of the increase in 1924 and 1925 was forthcoming, except the possible one that it might have been due to earlier and more correct diagnosis. It is well known that among the poorer class and in more congested areas the disease is more prevalent than in the outlying districts, and this is clearly demonstrated by the figures for last year, which show 1.45 deaths per 1,000 in the urban districts, compared with 1.98 in the city. Portions of the north side of the city are, and have

always been, the most generally affected. A prominent medical practitioner who has considerable experience in treating tuberculosis attributed the decline in mortality to improved methods of treatment and the steps taken to prevent infection. Much, he said, yet required to be done to reach a minimum, and he thought it all came back to the housing conditions of the people. Better housing and better conditions of living generally were the fundamental grounds on which the best progress could be made. Housing conditions in Dublin were lamentably bad, and it was in the slum areas that the disease took its biggest toll.

#### CANCER IN DUBLIN AND THE IRISH FREE STATE.

So far as cancer is concerned, the statistics show that there has not been any appreciable change in mortality in the last ten years in Dublin. The figures are:

|      |     |      |     |
|------|-----|------|-----|
| 1915 | 434 | 1921 | 426 |
| 1916 | 425 | 1922 | 419 |
| 1917 | 381 | 1923 | 461 |
| 1918 | 451 | 1924 | 474 |
| 1919 | 438 | 1925 | 471 |
| 1920 | 420 |      |     |

For the years 1915-24 the yearly average per 1,000 of the population of Dublin was 1.04, while for 1925 it was 1.07. The total deaths from cancer showed an increase—not, however, very pronounced—in the Saorstát in the last decade. The figures are:

|      |       |      |       |
|------|-------|------|-------|
| 1914 | 2,567 | 1920 | 2,588 |
| 1915 | 2,553 | 1921 | 2,609 |
| 1916 | 2,679 | 1922 | 2,525 |
| 1917 | 2,633 | 1923 | 2,730 |
| 1918 | 2,618 | 1924 | 2,903 |
| 1919 | 2,673 |      |       |

#### TUBERCULOSIS AND THE MILK SUPPLY.

An effort to improve the health of Limerick is being made by the corporation, and at an early date a dispensary for the free treatment of tuberculous patients will be opened. In that connexion the comments on the need of a pure milk supply are of interest. In regard to the dispensary itself a doctor and nurse will be employed, the sick will be visited in their homes, and chronic cases will be sent to suitable sanatoriums. £1,500 will be provided by the Government for equipment, and a special rate has been levied by the corporation in anticipation of the scheme being adopted. In an interview the Mayor of Limerick stated that for a number of years the Government had been asking the corporation to formulate a scheme for the city, but the request had been declined because of the expenditure. The corporation, he said, conferred with the county council with a view to its co-operation in getting dispensaries opened in different parts of the county, and the real reason for doing nothing was because the corporation could not come to terms with the county council. The dispensary would, he added, be confined to the city, but it would be of great assistance if the county council co-operated. The medical profession in Limerick considered that very unsatisfactory provision was made for the distribution of milk in the city. In the county dirty vessels were frequently used, and there was no proper system to ensure the milk would be delivered free of dirt. Cases at the district courts showed how very careless the milk vendors were in this respect. Utensils and carts were discovered in a deplorable condition, and in many instances vessels were found without any covering to keep out the dust.

The prevalence of dirty milk and its connexion with consumption are referred to in a report on Purdystown Fever Hospital, Belfast, written by the Belfast medical superintendent of health. He states that during the past ten years the number of cowsheds has been reduced from 160 to 97, and the number of cows from 3,000 to 1,469, so that only a small proportion of the milk supply is now produced in the city, whereas formerly at least one-third was produced there. The officers have no authority to inspect dairies outside the city. He adds that 299 samples of fresh milk were specially examined for tuberculosis, and seventeen of these (5.7 per cent.) were found to be infected. In seventeen cases two were from milk inside the city boundary.

## England and Wales.

### ST. THOMAS'S HOSPITAL LADY ALMONER'S DEPARTMENT.

In the report of the lady almoner's department of St. Thomas's Hospital for 1925 it is noted that the wage-earner can, from the age of 17, now "look forward to some allowance if ill, to a weekly sum if unemployed, to a medical adviser if sick, and later, if he marries, to some provision for his wife and family if he dies out of due time, or, if he and his wife live to 65, to a pension of £1 a week for life." However, as the report goes on to say, the benefits are on a limited scale, a number of people who still work for themselves or for relatives do not come under the insurance scheme, and patients of the professional or middle classes are outside all benefits. Thus there is still need for the help of the Samaritan Fund. Of the work of this fund and of the Northcote Trust the report gives a very full and interesting account, with illustrative cases of patients who have received benefit from the various departments. The activities cover a very wide range. Thus out-patients and casualties are visited at home. Under the Northcote Trust advice and assistance is given in 'carrying on the home while the breadwinner or housewife is in hospital. Convalescence and maternity are provided for. Assistance is given in the supply of surgical appliances and dentures. Tuberculosis and venereal disease cases are dealt with; and the Northcote Trust Hostel provides treatment for women and girls suffering from venereal disease or requiring social care and help. There is a note in the report of a special investigation now being undertaken by Dr. James Birley into the mental condition of some of the girls in the hostel, with a view to providing for their future training, occupation, or management. The lady almoner's department seems to be extremely well organized and complete.

### ALNWICK INFIRMARY.

The new wing of Alnwick Infirmary was opened recently by the Duchess of Northumberland. The extension consists of a five-bed ward, a single-bed ward, and five bedrooms. Many special sinks, stoves, and other fittings have been presented by friends of the institution, the remainder of the expenses of furnishing being met by a fête held on the same day, at which a sum of over £650 was raised. Dr. Scott Purves, who has been associated with the infirmary for more than forty years, gave an account of the history of the institution, which was founded as a dispensary in 1815; five years later the work was transferred to another building, which, in 1849, was used as a cholera house. In 1850 its name was changed to the Alnwick Infirmary, although it still acted chiefly as a dispensary. A new infirmary was built in 1908, and further enlargements had become necessary owing to the great advances of surgery and the custom of performing operations in places specially equipped for the purpose rather than in private dwellings. The work of the hospital had been considerably increased by traffic accidents, and the accommodation for the nursing staff had hitherto been inadequate, but with the provision of the new wing a considerable advance had been made.

### LIVERPOOL OPEN-AIR HOSPITAL FOR CHILDREN, LEASOWE.

At the Liverpool Open-air Hospital for Children at Leasowe, Cheshire, some 250 children suffering mainly from non-pulmonary tuberculosis are treated annually. But treatment for non-tuberculous crippling disease is being developed by means of out-patient clinics. In his report for 1925 the senior medical officer (Dr. T. Hartley Martin) says that 82.8 per cent. of all the patients admitted to the hospital were discharged with the disease quiescent: the least satisfactory cases were those of lupus. Artificial sunlight has been of use in the majority of cases treated, and has prevented relapse during the sunless months, but it has not helped to prevent the occurrence of lardaceous disease. Orthopaedic workshops have been established, so that splints and appliances can be made cheaply and expeditiously. It is hoped that the development of the out-

patient clinics will tend to prevent relapses. The maintenance costs of the hospital are covered by grants from the Liverpool Corporation, various local authorities, the Ministry of Health, and the Board of Education. But capital expenditure is met by voluntary subscription, so that the management is appealing for £13,000 to wipe out the debt which remains on the capital account.

### SPECTACLES FOR SCHOOL CHILDREN: NEEDLEWORK.

The London Central Spectacles Committee for aiding the local supply of spectacles to elementary school children has now been working for five years, and its latest report is satisfactory. Despite much unemployment during these last years there has been a steady improvement and less need for grants from the central committee to the local committees. There are twenty-three local committees; five years ago only seven of them managed to finance their local work, now no fewer than nineteen do so. Last year 25,555 spectacles were ordered for the children, and of these 89.8 per cent. were obtained. Arrangements have been made in some districts for the opticians to pay periodical visits to the schools to adjust the frames of spectacles and do minor repairs. This is a move in the right direction; it might be copied generally in school areas. The report quotes a reply received from the London County Council Education Committee on the subject of needlework.

"The Council's regulations at present prohibit the teaching of needlework by artificial light, except in cases in which the Council's medical officer is satisfied that the artificial light is sufficient for the teaching of needlework without involving risk of injury to the children's eyesight. Further, when on any occasion it is necessary to use artificial light during the time when instruction, according to the time-table, should be given in needlework, arrangements are made for an alternative lesson to be given. In order to avoid the necessity for too frequently departing from the time-table, head-teachers are required to make provision, where practicable, for instruction in needlework to be given before 3 p.m. on any given day. The Council has directed that special attention shall be drawn to these regulations, and that the conditions shall be borne in mind when time-tables are approved."

The honorary secretary of the London Spectacles Committee is Miss M. Frere, 20, Ladbroke Square, W.11.

### LOCAL AUTHORITIES AND CANCER.

Dr. W. D. Champneys, assistant medical officer of health for Willesden, has reprinted his memorandum on cancer which was embodied in the report for 1925 of the Willesden Health Department. After summarizing present knowledge of cancer, Dr. Champneys indicates what, in his opinion, local authorities can do, under their existing legal powers, in the way of controlling the disease. He divides his proposals under the headings propaganda, diagnosis, treatment, and research. For propaganda in the medical profession he admits that local authorities should convene meetings of local medical practitioners to consider means for controlling cancer; that post-graduate lectures and demonstrations by recognized authorities should be given; and that local authorities should establish cancer clinics. Propaganda among the general public should be carried out by leaflets, posters, advertisements, and articles in the press, and by lectures. For diagnosis municipal clinics would be relied on. Dr. Champneys thinks that the minimum requirements of a clinic would be a staff consisting of a surgical specialist, a radiologist, and the necessary number of nurses; beds for the temporary admission of suspected patients; and an x-ray equipment. Diagnosis should be free to all persons applying for it, with perhaps a small charge for a barium meal. The treatment given to patients should include conveyance by ambulance to and from hospital; deep x-ray therapy at a hospital established or subsidized by the local council; surgical treatment at the same hospital. Research work should be carried out either in connexion with the work of the departmental committee of the Ministry of Health or as independent investigations, such as the inquiry into varieties of cancer made at Leeds. Dr. Champneys bases his propositions on the statements that cancer is steadily increasing in Willesden, as in the rest of England and Wales, and that, although the true nature and origin of the disease is unknown, enough is known about the conditions under which it occurs and the symptoms to which it gives rise to form the basis of a successful scheme

for its prevention or cure in a great many cases. With no wish to damp enthusiasm, it may yet be pertinent to suggest that some estimates are desirable as to the cost of such a scheme.

#### THE MIDWIVES AND MATERNITY HOMES ACT (1926).

Our attention has been called to an omission in the summary of the provisions of the Midwives and Maternity Homes Act (1926) which appeared in our issue of August 14th last. Section 2, Subsection 2, of the new Act amends the wording of a subsection of Section 14 of the Midwives Act, 1918, relating to the payment of fees to medical practitioners called in to assist midwives in cases of emergency. The subsection now reads as follows: Subsection (2) of section fourteen of the Midwives Act, 1918 (which imposes a condition on the payment of a fee to a medical practitioner called in to assist a midwife in case of emergency), shall have effect as though at the end thereof there were added the words "and shall submit his claim within two months from the date on which he was called in." As Part I of the new Act comes into force at once, medical practitioners should remember, when called in to assist a midwife, that if they do not give notice within two months they may find that their claim is statute-barred.

## Correspondence.

### GROWTH AND DIET FOR BOYS AND GIRLS OF SCHOOL AGE.

SIR,—The work of the Medical Research Council on diets for boys during school age<sup>1</sup> is of the highest practical value to all who have the care of children, whether in the home or institution.

Dr. Corry Mann demonstrates the high value of milk, when added in sufficient quantities to "a basic diet of poor quality but adequate physiological value," to promote increased physical development. Boys who were having 1/4 pint of milk daily, as part of their basic diet, were found to gain, on an average, 1.84 inches and 3.85 lb. in the year.

Some of the lads were then given 1 pint of milk a day extra, with the result that they grew 2.63 inches, and gained 6.98 lb. in the year. Moreover, the increased rate of growth was maintained for the three years the experiment was carried out, the milk boys being 2.37 inches taller and 9.39 lb. heavier than the non-milk boys at the end of the three years. These valuable findings of Dr. Corry Mann add yet another stone to the building of the perfect man.

It is not claimed, of course, that milk is the only article of diet which produces and maintains growth. The boys who had 1 1/2 oz. butter were not far behind those who had 1 pint of milk. The boy daily supplied with 1/2 to 3/4 oz. of watercress weighed heavier, but did not grow more than the boy on the basic diet.

As a matter of interest, these results were compared with those of boys and girls (of the same age as those Dr. Corry Mann experimented with) who live under different conditions. His boys were under model conditions in an institution. These groups to be compared are in boarded-out homes in the country and in small branch homes. There are ten in each group. The observations cover a period of two years. One year's average is taken.

*Group A.*—Boys in boarded-out homes in country cottages gained an average of 2.33 inches and 6.65 lb. in a year.

*Group B.*—Girls under similar conditions to Group A, 2.32 inches and 7.05 lb.

*Group C.*—Girls in a small branch home, 2.30 inches and 7.15 lb.

*Group D.*—Girls in another small branch home, 2.14 inches and 6.70 lb.

In the boarded-out homes under review the children certainly do not have a pint of milk a day. Half a pint is what is aimed at. There are, however, more frequent suet puddings and fresh greens, such as lettuce. It has been noted in various reports that the boarded-out child tends to be tall, and the institution child stumpy. The child in the smaller branch home has, in one case, 1/4 pint

of milk, and in the other, milk a little in excess of that quantity. They hold their own in height and weight with the milk-fed boy. No butter is used. But there is only wholemeal bread in both, and in one rolled oats every day. The boys in the model colony have white bread, and porridge three times a week.

It is impossible to attribute growth to any one particular article of food. Milk, butter, suet, porridge, wholemeal bread, and fresh greens all make a difference when added in sufficient quantities. There is another influence which cannot be measured, and that is the personal supervision during meals which, however carefully it is tried to be maintained, tends to break down in large institutional life.

In one home, where the average rate of growth among ten girls was 1.75 inches and 5.4 lb. in 1924, it was found to be increased to 2.85 inches and 8.90 lb. in 1925. At the close of 1924 butter took the place of margarine, and wholemeal bread only was substituted for white factory bread. A handful of "sun-maid" raisins was given to each child every day, and almost every day of the year fresh fruit was doled out. Here is a difference which for one year, at any rate, exceeds the pace for the milk-fed boy.

What we do learn, however, from these figures is, first, that we must reasonably expect the child from 7 to 14 to gain 2 inches and 6 lb. in one year; second, that if he is not doing this, the diet he is being reared upon is deficient; third, that growth can be stimulated and maintained by the addition of many articles. (I am not going into the question of what can be curtailed from the diet.) It is taken for granted that personal hygiene, oral cleanliness, physical culture, fresh air and sunlight, judicious clothing, with happy and contented environment, have all been seen to. If strict attention is paid to all these matters to do with the child's health, a taller and heavier race will be produced, even when the foundations have been badly laid by early neglect and injudicious feeding.—I am, etc.,

A. H. MACDONALD,

London, E.1, Sept. 13th. Chief Medical Officer, Dr. Barnardo's Homes.

### THE PERIOD OF INFECTIVITY OF WHOOPING-COUGH.

SIR,—With the return of children to school in the near future an authoritative pronouncement is badly needed on this subject.

Medical officers of schools are in a dilemma. On the one hand they are told that infectivity of whooping-cough lasts "until two weeks after the last whoop," on the other that it ceases "four weeks from onset of catarrhal symptoms." Which is right? Recently a parent was given the first rule for his boy and the second for his girl, both of whom had had recent whooping-cough.

I believe medical officers of schools would welcome an authoritative pronouncement from a bacteriologist interested in Bordet's bacillus. Can Bordet's bacillus be isolated from the throat four weeks from the onset or not?

My own view is that, failing proof to the contrary, it is safer to exclude children until two weeks have elapsed since the last whoop. If the period of infectivity of four weeks only is regarded as correct, then a child may return to school with the whoop in full blast, for we all know that the whoop may not appear for three weeks or so after the child is suspect on account of a cough, etc. Again, a vaccine of a pure culture of Bordet's bacillus appears to me to act beneficially after the four weeks' period.—I am, etc.,

A. C. DEVEREUX.

Malvern, Sept. 9th.

### CHOLECYSTOGRAPHY.

SIR,—So much has been written and said recently regarding the advantages of cholecystography as a means of diagnosis in gall-bladder affections, that I think special attention should be drawn to a circular letter written by Mr. Martindale on August 9th.

As a preface to his letter he quotes a statement made by Professor Graham at the recent British Medical Association meeting to the effect that "Toxic reactions occurred in a certain number of cases after intravenous injection and

<sup>1</sup> BRITISH MEDICAL JOURNAL, August 14th, 1925, p. 317.

more after oral administration of the drug. . . .” Mr. Martindale then states that he has previously suggested the disuse of sodium tetraiodophenolphthalein as an intravenous injection, because in his opinion there will always be an element of risk with this chemical when used intravenously on human beings, however carefully it has been made and however carefully it is administered. He continues that if medical men still desire to use the substance in any form they will do so entirely on their own responsibility; and, moreover, in future he will not supply the drug for intravenous use.

Mr. Martindale is to be congratulated upon a very emphatic expression of his own conviction, and, coming from one of the greatest authorities in research work on pharmaceutical products, it is particularly significant.

Cholecystography is undoubtedly being widely practised in this country, and more especially in America, and the clinical and radiological investigations of affections of the bile passages have made rapid progress since its introduction. The opinion was expressed at Nottingham that it should become a standard method of investigation, but a little later the same speaker pointed out that very great care in technique was necessary to prevent reactions. Professor Graham stated that no death had been recorded following the injection, but Mr. Martindale tells us that the American literature abounds with references to toxic effects following its administration. Nearly all observers agree that reactions of a more or less severe degree occur in a certain percentage of cases, and various drugs have been advocated to counteract them. There is thus abundant evidence that there are very material dangers in what is, after all, only a diagnostic procedure.

I have used the iodine salt in about fifty cases, adopting the technique described by Graham. In a very substantial percentage of cases toxic reactions followed, varying in some from slight dizziness and nausea to repeated vomiting, a very appreciable fall in blood pressure, severe headache and collapse in others. In two cases, however, the symptoms became much more alarming. One patient became so ill that subsequent x-ray examination was deemed inadvisable, while the other towards the end of the administration suddenly became very ill, pulseless, and, in fact, one thought that she was going to die. She remained extremely ill for twenty-four hours in spite of most vigorous treatment, and for four days was as though recovering from a severe operation. Finally she left hospital, it being considered advisable to postpone operation. It is true that with the exception of this case no patient showed any untoward symptom on the day following the injection.

Alongside these cases, in all of which I have actually given the injection myself, a death has taken place at another hospital in this city. Following upon these experiences Mr. Martindale's letter came as no surprise. Apart altogether from the advantages and results of any test, it must be absolutely safe from a patient's point of view, and not until then can it be recognized as a routine method of diagnosis.

It appears to me, furthermore, that a most careful selection of patients has to be made, refraining particularly from employing cholecystography in elderly patients with a low blood pressure; but even then there remain patients who seem peculiarly intolerant to the drug.

Is it not probable that, just as in pyelography the use of sodium bromide has quite supplanted the irritant silver salts, we shall some day be furnished with a preparation free from any risk or even discomfort?—I am, etc.,

Birmingham, Sept. 4th.

CYRIL A. RAISSON.

#### SANATORIUM TREATMENT.

SIR,—In the JOURNAL of August 28th (p. 397) there appeared a review of a memoir on the influence of sanatorium and dispensary treatment and housing conditions on pulmonary tuberculosis, recently published in the *Annals of Eugenics*. My interest was aroused by the review, and I have now read the memoir.

I express no opinion as to whether the conclusions of the authors of the memoir will be confirmed by further investigation, or otherwise. But I would point out that their argument is invalidated by a most serious defect in

the data, on which they have spent so much ingenuity and labour. There are other defects—for example, that 29.1 per cent. of the “sanatorium treated” cases were lost sight of, and 51.6 per cent. of those “otherwise treated”; that fourteen days in a sanatorium was held sufficient for a case to be classed as “sanatorium treated”; and that for a patient to be classed as under “regular” medical treatment at the dispensaries the criterion was “not less than four visits per year with a minimum of three months’ treatment.”

But the great defect to which I refer is the want of information as to the presence or absence in each case of sputum containing tubercle bacilli. On the fifth page of the memoir the following statement is made:

“It was found impracticable to use the presence or absence of tubercle bacilli in the sputum as more than an adjuvant in diagnosis, since the number of cases in which bacilli were sought for and found was relatively small. Thus the percentages of cases in which the diagnosis was thus confirmed were:

|                | Li. | Lz.  | La.  |
|----------------|-----|------|------|
| Males ... ..   | 6.1 | 13.1 | 19.0 |
| Females ... .. | 4.2 | 10.8 | 11.9 |

Investigation of county Down cases has shown me that among patients suffering from pulmonary tuberculosis who have survived for more than six months from the time when they first came under observation, there has been an enormous difference, as regards both survival and recovery of working power, between cases in which tubercle bacilli were found in the sputum and those in which, though sought for, they were not found. Hence it is unscientific to lump these two classes together without any indication of the relative proportions of each class in the various subsections tabulated in the memoir.

In any investigation of this kind, T.B.+ and T.B.—cases should be kept quite separate, and data which do not permit of this being done should be avoided.—I am, etc.,

JOHN R. GILLESPIE, M.A., M.D., D.P.H.,

Tuberculosis Medical Officer, County Down.

Knock, Belfast, Sept. 8th.

SIR,—Judging from your review of Dr. Stocks's work on sanatorium treatment, it appears that, if all other factors have been rightly evaluated, its chief worth is the knowledge it gives that sanatorium treatment as administered in the North of Ireland is unsuitable for the people who live there. In England nobody who had received sanatorium treatment for less than two months would have been included.

Another and a most important consideration will occur to everyone who has done general sanatorium work. This is that the Irish are, as a rule, the worst sanatorium patients we meet with.—I am, etc.,

August 28th.

MÉDECIN POITRINAIRE.

#### HARVEY AND THE LANCASHIRE WITCHES.

SIR,—In your interesting article (August 14th, p. 311) on a Harveian Tercentenary you refer to Harvey's association with the trial of the four Lancashire witches in 1634, but it was not on Harvey's judgement alone that their fate was decided. Their story as it can be traced by documents preserved at the Record Office is interesting.

Throughout the seventeenth century belief in witchcraft was very general, and in the spring of 1634 a serious outbreak of that offence, as it then was, occurred in Lancashire.

A letter dated May 16th, 1634, written by Sir William Pelham of Brocklesby to a friend, says there had been discovered “a huge pack of witches in Lancashire wherein it is said 19 are condemned and at least 60 already discovered; there are divers of them of good ability and they have done much harm. It is suspected that they had had a hand in raising the great storm wherein his majesty was in so great danger at sea in Scotland.”

The women examined by Harvey and others were the survivors of a batch of seven, three of whom had died in

gaol, and they had already been examined by Bishop Bridgeman of Chester as to their spiritual condition. The evidence given before the bishop of their intimate relations with the devil is amusing to read now, but it was a very serious matter in 1634.

The women were brought to London in charge of the under-sheriff of the county. A letter dated from Whitehall, June 29th, 1634, and addressed to Alexander Baker, Esq., and Sergeant Clowes, Esq., His Majesty's surgeons, directed them "to make choice of midwives to inspect and search the bodies of those women lately brought up by the sheriff of the county of Lancaster, indicted for witchcraft, wherein the midwives are to receive instructions from Mr. Dr. Harvey, the King's physician and themselves." This letter is signed by Henry Montagu, Earl of Manchester, Lord Privy Seal; Sir John Coke; and Sir Francis Windebank, who were the principal Secretaries of State, and is endorsed, "The prisoners are at the Shippe Taverne, Greenwich." In obedience to this letter the prisoners were examined, probably at Greenwich, and the following certificate was sent to the Council:

"July 2nd, 1634. Surgeon's Hall, Mugwell Street, London. That in humble obedience to the Council and by the direction of Mr. Dr. Harvey and in his presence, they have made diligent search and inspection on those women lately brought up from Lancaster and find as follows: On the bodies of Janet Hargraves, Frances Dicconson, and Mary Spencer nothing unnatural nor anything like a teat or mark. On the body of Mary Johnson they find two things which may be called teats; the first in shape like the teat of a bitch, but in their judgment nothing but the skin of the fundament drawn out as it will be after the piles on the application of leeches; the second is like the nipple or teat of a woman's breast, but of the same colour as the rest of the skin, without any hollowness or issue of any blood or juice to come from thence."

This certificate is signed by William Clowes and Alexander Baker, and by five other surgeons and the midwives, but is not signed by Harvey. Alexander Baker was Master of the Barber-Surgeons in 1622. William Clowes was Sergeant-Surgeon to the King, and Master of the Barber-Surgeons in 1626 and again in 1638. He was the son of William Clowes (1544-1603), Surgeon-General to Queen Elizabeth, and surgeon to St. Bartholomew's Hospital.

The certificate probably helped to liberate the women, but the evidence given against them was very unreliable and grotesque. Two of the chief witnesses were Edmund Robinson and his son Edmund, a boy of about 10 years of age. The boy had told some marvellous stories, but on July 10th, when examined before George Long, justice of the peace for Middlesex, made a recantation of his evidence, and said that he had told the tales about the women to excuse himself when he had been at play. The father was imprisoned, and there are several references to appeals for his release. I do not find any account of a formal trial in court of the women, and they were probably liberated soon after Harvey's examination. On July 4th, 1634, at a meeting of the Council at Whitehall, Robert Maudesley, the under-sheriff who brought up the witches from Lancaster, was discharged from further attendance, and it was ordered by the Lord Treasurer that he should be rewarded.

During the seventeenth century trials for witchcraft were very numerous. The last trial in England was in 1712, and the laws against witchcraft were repealed, 10 George II (1736).—I am, etc.,

London, N.W.3, Aug. 26th.

H. A. CLOWES.

#### CAN BEACH BATHING BE MADE SAFER?

SIR,—The numerous bathing tragedies that occur around our coasts in the summer season raise the question whether the precautions taken are adequate to meet the risk of sudden and unaccountable drowning. The causes of drowning under the conditions of beach bathing may be set down in four categories.

1. Sudden loss of consciousness due to syncope or temporary heart failure.

2. Loss of consciousness due to an epileptic fit. In themselves these causes are not necessarily fatal when they occur on land, but in water, even of very moderate depth, drowning occurs owing to the helpless condition of the person. While these causes

account for a few of the fatalities, there are two other causes which account for the vast majority—namely:

3. Cramp or painful rigid spasm of the voluntary muscles.

4. Sudden fright accompanied by complete loss of confidence, a sense of helplessness, and a paralysis of the will.

Three and four may be combined. Cramp does not seize the four limbs simultaneously; if this did occur the person would be as helpless as if attacked by the two first mentioned causes. As a rule one limb is seized, then there supervenes a depressing feeling of loss of confidence, and if there is no support near at hand to which the bather can cling he struggles in a more or less frenzied state and sinks. A similar mental state is often induced when a bather is swept out of his depth by the strong undertow of a breaker.

The moral of this is that beach bathing could be made much safer if provision were made so that bathers in temporary difficulties could easily cling to some support near at hand. The present precautions of prohibiting certain portions of a beach and of providing beach watchers and men in boats are insufficient. Drowning in these cases takes place with extreme rapidity. In less than five minutes a healthy vigorous person becomes a corpse. What is required is something to help the bather to help himself at the moment of temporary difficulty. A drowning man will clutch at a straw, and I suggest that this effort indicates the means by which beach bathing could be made more safe.

If a portion of a beach were taken and strong wooden posts were driven into the sand at suitable intervals apart, from low-water mark to high-water mark, a wire rope stretched across these posts and anchored beyond low-water mark and stretched tight to a fixture above high-water mark would provide a means whereby small hempen ropes with floats attached could be suspended to the water level. It may be said that some rash persons would not bathe in the area equipped for safe bathing, but while that may be so, the responsibility for disaster would not lie with the local authority which had made such provision.

It may surprise some to know the numbers drowned yearly while bathing. The Registrar-General reports that the number of deaths from drowning was as follows:

|      |     |     | Males. |     | Females. |
|------|-----|-----|--------|-----|----------|
| 1917 | ... | ... | 231    | ... | 9        |
| 1918 | ... | ... | 153    | ... | 19       |
| 1919 | ... | ... | 177    | ... | 16       |

It may be assumed that the majority of these persons were healthy vigorous individuals in the early or middle period of life. The cost of the suggested equipment is not great, certainly not great to those much advertised seaside resorts where thousands of pounds are spent on questionable amusements.

Beach bathing is a healthy and joyous recreation, and any suggestion to lessen the annual toll of heart-breaking tragedies should be welcomed.—I am, etc.,

September 1st.

NETTUNE.

#### PUERPERAL FEVER AND PUERPERAL PYREXIA.

SIR,—I wonder if practitioners fully realize the amount of work which is imposed upon them by the recent Order relating to the above conditions. Not only are they required to notify the case, but they may also have to furnish a complete report on the condition of the patient prior to the confinement, the names of those who have made vaginal examinations, the clinical course of the labour or miscarriage, amount and character of the lochia, copy of temperature chart, etc., and all for 2s. 6d., less the cost of postage—that is, 2s. 4½d. To be sure that the case is notifiable some reliable person must take the temperature during a period of twenty-four hours.

Although I am all in favour of doing all that can be done to ascertain the cause of puerperal fever or pyrexia, I do not think the doctors should be called upon—nay, compelled—to give so much time and skill for the ridiculous fee of 2s. 6d. As the necessary report is to be so full I suggest 7s. 6d. as being the least that should be paid. I have personally no financial interest in the matter as I have ceased to take midwifery cases.—I am, etc.,

Plymouth, Sept. 4th.

S. NOX SCOTT.

## APPENDICITIS AND VEGETARIANISM.

SIR,—The increase of appendicitis during the present century has been attributed to the increased consumption of imported meat, both tinned and frozen, and the decreased consumption of vegetables containing a plentiful supply of cellulose.

If this theory were correct we would expect to find vegetarians immune from the disease. At the present time I have a case under my care of acute gangrenous appendicitis in a boy of 10, whose parents and himself have been life-long vegetarians.

I am interested to know if this case is an exception.—I am, etc.,

Birmingham, Aug. 25th. HAMILTON BAILEY, F.R.C.S.Eng.

## GONGYLONEMA AND CANCER.

SIR,—The only reply to Professor Leiper's letter that seems to be necessary is the statement that my views on the synonymy of the various species of *Gongylonema* are based upon evidence which I have published in full. Professor Leiper, so far as I am aware, has not yet made public the evidence which leads him to differ from me.

As a zoologist, I have never ventured to express a personal opinion on the causation of cancer.—I am, etc.,

British Museum (Natural History),  
London, S.W.7, Sept. 11th.

H. A. BAYLIS.

## Obituary.

HERBERT WILLIAM PAGE, M.A., M.Chir., F.R.C.S.,  
Consulting Surgeon, St. Mary's Hospital.

WE regret to record the death of Mr. Herbert William Page, consulting surgeon to St. Mary's Hospital, which took place at Farnham on September 9th, after a long illness, in his 81st year.

He was the eldest son of William Bousfield Page, F.R.C.S., of Carlisle, and was born on December 22nd, 1845. He entered Edinburgh University in 1864, and subsequently went to Christ's College, Cambridge, where he graduated B.A. in 1868, M.B. in 1870, and M.A. in 1872; he became Master of Surgery in 1873, having obtained the Fellowship of the Royal College of Surgeons in 1871. He was a student at the London Hospital, and was house-surgeon to Sir Jonathan Hutchinson. Amongst his teachers were Sutton and Hughlings Jackson, from the latter of whom he derived his interest in neurology. He studied also at Vienna.

On the outbreak of the Franco-Prussian war, Page volunteered and joined the German army as assistant surgeon in the Hessian Division, serving at the Princess Alice Hospital at Darmstadt. When he returned to England he joined his father for a short time in practice at Carlisle; but in 1875 he was appointed surgical registrar at the London Hospital, and in the following year became assistant surgeon to St. Mary's Hospital. In 1881 he won the Boylston Medical Prize at Harvard University for his essay on "Injuries of the back, without apparent mechanical lesions, in their surgical and medico-legal aspects." A second edition was published in 1885 under the title "Injuries of the spine and spinal cord, without apparent mechanical lesions, and nervous shock in their surgical and medico-legal aspects."

From 1899 to 1907 Mr. Page served as a member of the Council of the Royal College of Surgeons of England, and was for eight years a member of the Court of Examiners of that body. He was also examiner in surgery at the Universities of Oxford, Cambridge, and Birmingham. He served as president of the Neurological Society, an unusual position for a surgeon. But the work in which he chiefly distinguished himself was as an expert in conditions arising from injuries in railway accidents. As surgeon to the London and North-Western and Great Western Railways he devoted much time to the investigation of symptoms produced by such injuries, and in his frequent appearances as witness on behalf of these companies he displayed great logical power and knowledge of medicine.

He was a straightforward witness, forming his opinions carefully, and adhering to them strongly and clearly when formed. Moreover, his tact and courtesy when called upon to meet witnesses on the other side must frequently have saved his companies from unnecessary appearances in court. Page devoted much attention to the condition known as "railway spine," or "concussion of the spine"; and with no uncertain eye could recognize the cases in which cure was likely to be effected speedily by heavy damages. It was in cases such as these that he employed his powers of persuasion in the endeavour to prevent medical experts on opposite sides from lowering the prestige of the profession.

Page's highly original views on "railway spine" gave rise to great controversy in the medical profession, and were opposed by those who supported the opinions of Professor Erichsen. The views were embodied in the Boylston essay which gained the Harvard prize, and were subsequently elaborated in Page's book, *Railway Injuries*. It was as a result of his work that traumatic neurasthenia came to be better recognized; and though the war has greatly increased the stock of remedial measures, the curative effect of legal damages still remains.

Page's surgical work in connexion with injuries of the head has been described as unequalled among his contemporaries. It was conscientious and careful, and of great value to his students. His lectures were clearly reasoned and scholarly, if not dramatic. Of the assistance he gave in raising the medical school at St. Mary's to its high position there can be no doubt; no less certainly must Page be regarded as a pioneer among those experts in medico-legal matters for whom the school is now so famous. At the Annual Meeting of the British Medical Association held at his birthplace—Carlisle—in 1896 he was vice-president of the Section of Surgery; and at the Ryde meeting in 1881 he had acted as honorary secretary of the same Section.

As Page never sought to enter the limelight, his name is not connected to any extent with public affairs; but he was a justice of the peace for Surrey. His first wife was a daughter of the Rev. Christopher Parker of Skirwith Abbey, Cumberland. In 1905 he married Kathleen, daughter of Canon Houghton. He leaves two daughters by his first wife; and he is survived by all his brothers—Mr. Ernest Page, K.C., Recorder of Carlisle and Benchers of the Inner Temple; the Very Rev. Arnold Page, Dean of Peterborough; and Mr. Lawrence Page, until lately solicitor to the Great Western Railway Company.

S. A. POWELL, M.D.,

Formerly Professor of Medical Jurisprudence, Grant Medical College, Bombay.

DR. SAMUEL ARTHUR POWELL, O.B.E., V.D., died suddenly at Sutton on August 28th, aged 62. He had been in the Oriental Club, in his usual health, for some time on the previous afternoon. He was educated at Trinity College, Dublin, and at Belfast, and graduated as B.A. in the natural sciences tripos in 1885, and as M.B., M.Ch., and M.A.O. of the Royal University, Ireland, in 1887. After qualifying he was for many years a planter's doctor in the tea districts of Assam. In 1899 he went to South Africa in Lumsden's Horse, the corps raised in India, chiefly from among the planters, by Colonel Lumsden, for service in South Africa. He was mentioned in dispatches, received the Queen's medal with three clasps, and received a commission as honorary captain in the army. On his return to India he was appointed police surgeon of Bombay, and professor of medical jurisprudence and biology in the Grant Medical College, Bombay. He was also a justice of the peace for that city, a fellow and examiner of Bombay University, consulting physician to St. George's Hospital, Bombay, and inspector of lepers, Bombay; and held a commission as lieutenant-colonel in the Indian Defence Force, formerly Indian Volunteers. He had received the Indian Volunteer officer's decoration. During the great war he was commandant of the Byculla officers' hospital in Bombay, was mentioned in dispatches, and received the O.B.E. Retiring under the age limit a few years ago, he

set up as a consultant in Harley Street, and was consulting physician for tropical diseases to the Ministry of Pensions.

The above outline of Dr. Powell's career may be supplemented by extracts from an appreciation of his work and character sent us by a friend:

"Dick" Powell, he writes, was no doubt better known in India than in this country, but his brilliant qualities had won for him here also a high reputation for scientific skill, as well as the affection of a wide circle of friends. He had to an extraordinary degree the power of winning true and abiding friendships. In 1888 he sought a career in India as medical officer in North-West Cachar. There he saw an extraordinary diversity of practice, but he threw himself into the work with all the zest of his nature, and yet found time to attend to bacteriological studies, which fascinated him. As a professor in Bombay he had the faculty of making his lectures very interesting, both by the originality of his treatment and by his eminently practical demonstrations, and his memory will always be cherished with great affection by his old students. He did valuable work also in the Senate of the University of Bombay, and his friends often recalled his witty and piquant speeches whenever he had to deal with obstructionists. His range of knowledge was extraordinary, and in India he carried out a far greater number of operations for cataract than most eye specialists could boast of. On one occasion he operated successfully on an elephant, and the great animal used afterwards, when he saw him, trot over and follow him like a dog. His principal achievements in medicine, however, consisted in a series of his observations in yaws, which resulted finally in the best description and definition of that disease that we possess. For one thing, he clearly differentiated the lesions of yaws from those of syphilis. When Schaudinn discovered the spirochaete of syphilis in 1905 Powell had his specimens examined for a similar organism, with positive findings, though Castellani's discovery of the organism found precedence in time. Powell showed that the invasion of syphilis had taken place as a subsequent infection in well defined cases of yaws. His medico-legal work in Bombay soon earned him not only distinction but popular fame, for in addition to his expert knowledge he added a keen insight into human nature and an intimate acquaintance with local conditions. One of the results of his observations was that it was not so much opium as alcohol and cannabis indica that caused crime and degeneracy in India. His papers at the Royal Society of Medicine and elsewhere were greatly appreciated, not only for the matter, but for the style. He might have acquired a bigger position in the world's eye but for his innate modesty; but all these things will not now matter to his friends, who will rather remember "Dick" Powell for that spirit of kindness which went so well with his unselfish and genial nature.

Mr. CECIL JOHN DAVENPORT, who died suddenly in Shanghai on September 4th, aged 65, was born in Adelaide, South Australia. He received his medical training at St. Bartholomew's Hospital, whence he obtained the diplomas M.R.C.S., L.R.C.P. in 1887, and the F.R.C.S. Eng. in 1889, in which year he went to China as a medical missionary of the London Missionary Society. He worked first in Chungking and later in Wuchang, and in 1905 was appointed medical superintendent of the Shantung Road Hospital, Shanghai, a large voluntary hospital for the Chinese. This post he held till his death, and under his superintendence the hospital extended its activities and improved in efficiency; it became also a training centre for doctors and nurses. Recently the hospital received £5,000 under the will of the late Mr. Henry Lester of Shanghai (JOURNAL, July 24th, p. 166), and it was hoped that Mr. Davenport's guidance and judgement might be given to the trustees in its administration. Mr. Davenport was a kindly man, with high Christian principles; his life was devoted to his work without desire for personal distinction, and his loss will be felt by all classes in the community where he lived. The value of his labours was

recognized by the Chinese Government, which bestowed upon him a decoration, and he was a past president of the China Medical Missionary Association. He married in 1890 Miss Miles, who was before marriage Sister Martha at St. Bartholomew's Hospital. He is survived by his widow and three children, of whom one, Mr. R. C. Davenport, is an ophthalmic surgeon in London.

Dr. JOHN JONES GASPERINE, who died on August 13th, at the age of 36, as the result of a bathing accident at Long Island, in the United States, was born in Ireland and received his medical education at Edinburgh and St. Bartholomew's Hospital. He obtained the diplomas M.R.C.S., L.R.C.P. in 1916, the D.P.H. in 1921, and the D.P.M. in 1922. He served with the Royal Navy from 1914 to 1919, and had held the appointments of house-physician and house-surgeon at St. Bartholomew's Hospital, assistant pathologist at the London Lock Hospital, house-physician and house-surgeon at St. Andrew's Hospital, Dollis Hill, assistant medical officer to the London County Mental Hospitals, and medical superintendent of the Norwood Sanatorium, Woodbridge. At the time of his death he was attached to the Cunard Line as surgeon. He was a member of the British Medical Association and of the Medico-Psychological Society of Great Britain and Ireland. A colleague writes: Dr. Gasperine was a man of singular kindness and charm. He had a quiet unassuming personality; his wide professional experience and knowledge of the world in general endowed him with a skill and wisdom more to be expected in a man of maturer years. He had made many friends on both sides of the Atlantic who will mourn his loss.

Dr. TOM BOWER FAWLEY of Hull, who died on August 22nd, received his medical education at Guy's Hospital and obtained the diplomas M.R.C.S., L.R.C.P. in 1902. After serving as assistant to Dr. A. Hawkyard of Leeds he started practice in Hull about twenty years ago, and was appointed visiting surgeon to the Hull and Sculcoates Dispensary. He built up a large practice among the industrial classes, by whom he was highly esteemed. He was much interested in music, had a fine tenor voice, and was an accomplished violinist. He was a member of the East York and North Lincoln Division of the British Medical Association.

## The Services.

### SURGEON REAR-ADMIRAL BEADNELL'S RETIREMENT.

The brief notice among "Naval and Military Appointments" last week that Surgeon Rear-Admiral C. B., K.H.P., R.N., had been placed on the retired list at his own request. The notification appeared in the *London Gazette* of August 24th. At the time of his retirement Surgeon Rear-Admiral Beadnell was the senior of the six medical officers of that rank on the active list, having been promoted to it in February, 1922, while still in his 50th year. He entered the navy in 1896, and as surgeon of H.M.S. *Powerful* saw active service both during the Philippine war of 1898 and with the Naval Brigade in the South African war. For his work in the Boer war he was awarded eight years' special promotion to the rank of staff surgeon. In 1904 he was promoted fleet surgeon. During the first three years of the great war he served in H.M.S. *Shannon*, flagship of the Second Cruiser Squadron. In 1922 he was British representative of the Army and Naval Medical Departments at the International Congress of Surgeons held in Washington. In the following year he received the appointment of P.M.O. commanding the Royal Naval Hospital, Chatham, and naval member of the Medical Consultative Board of the Admiralty. He was created C.B. in 1924. His retirement, nearly six years before attaining the age limit for his rank, will facilitate the promotion of his juniors, but removes from the navy an active-minded and able medical officer with a fine record of service afloat and ashore.

### DEATHS IN THE SERVICES.

Lieut.-Colonel William James Fraser, I.M.S., died of cholera at Raipur, Central Provinces, on August 19th, aged 45. He was born at Bannachie, Ceylon, the third son of the late John Fraser of Abbotsford, Ceylon, and of Bridge of Allan, and educated at Edinburgh, where he graduated as M.B. and Ch.B., with honours, in 1904; he also took the university diploma in tropical medicine and he took the F.R.C.S. Ed. in 1908, and the I.M.S. as lieutenant in 1925. He entered the I.M.S. as lieutenant-colonel on August 1st, 1925. He served in the great war of 1914-18, and was mentioned in despatches in the *London Gazette* of June 5th, 1919.

## Medical News.

THE next international congress of surgery will be held at Warsaw in July, 1929, under the presidency of Professor Hartmann of Paris.

THE new baths at Leamington Spa will be opened on Saturday, October 9th, by Sir H. Kingsley Wood, M.P., Parliamentary Secretary, Ministry of Health. The ceremony will take place in the Royal Pump Room at 3 o'clock.

THE opening ceremony of the winter session at King's College Hospital Medical School (University of London) will be held on Friday, October 1st, at 2.30 p.m. The introductory address will be given by Sir Humphry Rolleston, Bt., K.C.B., M.D., Regius Professor of Physic in the University of Cambridge. The annual dinner of past and present students will be held at 7 for 7.30 on the same day at the Criterion Restaurant, Piccadilly, W.1, with Dr. Frank H. Jacob in the chair.

THE inaugural address at the Westminster Hospital Medical School will be delivered on Friday, October 1st, at 3 p.m., by Sir Archibald E. Garrod, K.C.M.G., F.R.S., Regius Professor of Medicine in the University of Oxford. The proceedings will take place in the board room of the hospital, and tea and coffee will be served afterwards.

THE Association of Special Libraries and Information Bureaux will hold its third week-end September 24th to 27th at . . . Papers are to be given on various . . . collection and distribution of information by experts, including Dr. de Vos Van Steenwijk, of the League of Nations, and Mr. Kaiser, of the Engineering Societies' Library, New York, who will speak on systematic indexing. The British Medical Association will be represented by its Intelligence Officer, Miss A. L. Lawrence, M.A., LL.B.

DURING and after the second week of October three series of clinical lectures illustrated by cases will be given at the Maudsley Hospital, Denmark Hill, S.E.5, at 2.30 p.m. On Mondays Dr. W. Moodie will lecture on the relations of mental disorder to physical conditions, on Wednesdays Dr. Edward Mapother on neurotic and psychotic syndromes, and on Fridays Dr. W. S. Dawson on mental symptoms and their genesis. In addition a discussion on cases in the Mental Hospital is held in the wards every Tuesday at 11.30; and monthly, on the last Friday of each month, at 4.30, at which a group of patients from one of the London County Council Mental Hospitals is shown. These lectures and discussions are open to medical practitioners without fee. Posts as clinical assistant can be obtained on application to the medical superintendent. The course of lectures and practical instruction for the diploma in psychological medicine will be held at the Maudsley Hospital, beginning in January next. The lectures and demonstrations are given in series, and either group can be attended separately. The fee for the course is ten guineas, or for a single series two guineas, payable to the Fellowship of Medicine, from which office (1, Wimpole Street, W.1) copies of the syllabus may be obtained.

THE lectures arranged by the British Institute of Philosophical Studies for the forthcoming session, beginning October 4th, include ten lectures on medical psychology by Dr. T. W. Mitchell and a course on general psychology by Professor C. W. Valentine. In the Lent term Dr. C. Delisle Burns will lecture on the philosophy of social life, and Professor J. S. Mackenzie on social values, and the Dean of St. Paul's has promised to give a course of six lectures on the philosophy of religion in the summer term. The syllabus of lectures can be had on application to the Director of the Institute, 88, Kingsway, W.C.2.

THE sixth French Congress of Industrial Chemistry will be held at Brussels from September 26th to 30th, under the presidency of Dr. Gilbert, when questions of industrial hygiene will be discussed in the sixth section. Further information can be obtained from the General Secretary, 65, Rue du Canal, Brussels.

A COMPREHENSIVE course dealing with cancer will be held at Strasbourg from October 18th to November 6th, and will include practical work in the use of x rays, radium, and diathermy; the general principles of treatment; lectures on cancer affecting different parts of the body; and clinical demonstrations. The fee is 250 francs, and further information may be obtained from Dr. Gunsett, Hôpital Civil, Strasbourg.

A MEMORIAL tablet has recently been placed on the house in the Luisenstrasse, Berlin, formerly occupied by the Reichsgesundheitsamt, where Koch discovered the tubercle bacillus.

COUNCIL meetings of the Medical Women's International Association were held in Prague on August 26th and 29th. The President, Lady Barrett, took the chair, and reports of the activities of the various national associations were presented by the respective national corresponding secretaries. The most recently formed association was that of Hungary; and Hungarian delegates attended the meetings for the first time, and presented an excellent report. In addition to the other business of the council, medical meetings were held at which the subjects of tuberculosis and pregnancy, and women as police surgeons were considered. Representatives from the Czecho-Slovakian Ministry of Health attended these and took a prominent part in the discussions, a full report of which will be published in the current number of the *Medical Women's International Journal*. The president gave a dinner on the night preceding the council meeting, at which she welcomed the Lord Mayor and other officials and delegates. The association was also fortunate in having been invited to hold all the meetings in the Old Town Hall. The Lord Mayor and town councillors received the delegates and entertained them at a luncheon party; and the State Railways and Ministry of Health arranged a full programme, granting facilities to visit various spas, hospitals, and institutions.

THE list of candidates for election to the Royal Infant Orphanage, Wanstead, E.11, is now open. Children of both sexes who have lost both parents or the father only, and who are under 7 years of age, are eligible and are received from all parts of the United Kingdom. Applications should be addressed to the secretary at the orphanage.

## Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to *The EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1.*

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *BRITISH MEDICAL JOURNAL* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *BRITISH MEDICAL JOURNAL* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the *JOURNAL*, should be addressed to the Financial Secretary and Business Manager.

THE TELEPHONE NUMBERS of the British Medical Association and the *BRITISH MEDICAL JOURNAL* are MUSEUM 3361, 3362, 3363, and 3364 (internal exchange, four lines).

THE TELEGRAPHIC ADDRESSES are:

EDITOR of the *BRITISH MEDICAL JOURNAL*, Aitology Westcent, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate Westcent, London.

MEDICAL SECRETARY, Mediscera Westcent, London.

The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 4737 Dublin), and of the Scottish Office, 6, Drumshugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 4361 Central).

## QUERIES AND ANSWERS.

DR. CHARLES LANT SANSON (Port Health Office, Calcutta) writes in reply to "P. S. H." (*JOURNAL*, July 31st, p. 235), who asked for a method of killing fleas in his home: I was bothered with fleas in South Africa—tried sulphur and chlorine fumigation and other means, and failed until I used calcium hypochlorite. This was spread all round the rooms and brushed into the centre, and in a short time all the fleas disappeared.

### X-RAY TREATMENT OF RINGWORM.

DR. H. HALDIN-DAVIS (London, W.) sends the following reply to the query by "T. E. R." in our last issue (p. 511): For the most part aluminium filters are used in the x-ray treatment of ringworm in America because there, owing, I understand, to the dryness of the atmosphere, the Sabouraud pastille does not work so well as it does here and on the continent of Europe. Here there is no need for filtered rays if the pastille be properly used. The difficulty is to judge the tint correctly under varying conditions of light. This difficulty is much lessened if a Lovibond tintometer be used; it is made by Lovibond of Salisbury, who are specialists in colorimetry. I have used it in over 700 cases without a mishap. I have never used filtered rays myself, but I understand that when they are employed the pastille is exposed to the filtered rays and brought to 4/5 tint B, as with unfiltered rays. In America they employ other methods of measurement of the dose, owing, as stated above, to the unreliability of the pastille.

## ETIOLOGY OF MENTAL DISEASE.

"F. O. S." asks what is the best and latest work on insanity as showing that insanity and other abnormal mental conditions are due to structural alterations in the brain caused by disease or injury or other defect?

\* \* \* That insanity and other abnormal mental conditions are due to structural alterations in the brain is a thesis now seldom advanced in psychiatric textbooks. The proposition, as it stands, is, in our present state of knowledge, unproven. Most observers, however, firmly believe that in all such conditions there is some functional disorder of the brain, presumably of a biochemical nature; and that there may, of course, be simultaneous functional derangements of the endocrine organs and the vegetative nervous system, which are possibly causative. There is no gainsaying the unsatisfactory nature or the theory of the psychogenesis of certain mental disorder, of which Bleuler is perhaps the leading exponent; for where there is a psychogenesis there must indubitably be physiological reasons why the brain should be vulnerable. The late Sir Frederick Mott was perhaps the leading exponent of a purely materialistic interpretation. His views are to be found in his many lectures and addresses, most of them published in our columns during the last few years. Dr. J. S. Bolton, in *The Brain in Health and Disease*, and in many recent writings, is a vigorous advocate of similar views. Almost all recent textbooks (for instance, that of Craig and Beaton, reviewed in our issue of June 26th, 1926, p. 1088) consider all theories, and the necessary arguments may be abstracted therefrom. Tanzi's *Textbook of Mental Diseases*, which was translated into English in 1909, would still answer our correspondent's purposes very well. So far as we can ascertain, there has been no more recent edition of the English translation.

## INCOME TAX.

"MEDICUS IN A BRITISH COLONY" proposes to spend rather more than a year in England and on the Continent in doing some post-graduate work. He inquires whether he will be liable to income tax in the United Kingdom in respect of income derived from colonial investments.

\* \* \* No—provided that he does not spend six months in this country in any one financial year. (N.B.—The financial year commences on April 5th.)

"J. D. B." inquires why relief in respect of wear and tear and upkeep of a motor car is allowed to a private practitioner and not to an army medical officer who uses a car in his professional work.

\* \* \* The former's earnings fall under Schedule D and the latter's under Schedule E, and, as different rules apply to the two schedules, seeming anomalies occur sometimes. If "J. D. B." uses his car "wholly, exclusively, and necessarily in the performance of the duties of his office," he should be allowed to deduct the running cost. Judicial decisions have excluded the expense of travelling between the residence and the place of work from the allowance.

"T. C. L." replaced his car in 1925, the replacement cost being £290; the inspector of taxes proposes to allow this sum as a professional expense of the year 1925, but assumes that that will affect the 1926-27 assessment only.

\* \* \* Presumably the inspector is assuming that the three years' average will cease to operate for 1927-28; that is the existing intention, but it is perhaps not certain that the change will then be made, and in any event the accompanying provisions for relieving hard cases might assist "T. C. L." As regards the depreciation (20 per cent.) allowance on the new car, we are of opinion that an allowance of £87 should be given as for 1926-27; the ground for withholding it is no doubt that depreciation and replacement allowances cannot be given simultaneously, which is correct, but may be met by pointing out that the claim to deduct the £290 may be regarded as made under the statutory provision for an "obsolescence" allowance.

## LETTERS, NOTES, ETC.

## POST-GRADUATE HOSTEL.

MR. A. P. BERTWISTLE, F.R.C.S.Ed. (honorary secretary of the Hostel), writes: The Post-Graduate Hostel, Imperial Hotel, Russell Square, W.C.1, is arranging for a series of discussions on anatomical and physiological topics, in order that a graduate may have the opportunity of hearing the views of teachers from schools other than his own. Their purpose will be to show the practical value of these subjects, and they should therefore interest the body of the profession, besides making the subject more interesting to the graduate studying them. The first of these will be on Tuesday next, September 21st, when Professor F. R. S. Frazer (St. Mary's) will open the discussion on "Some clinical bearings of embryology."

## CANCER IN FAMILIES.

DR. ALFRED PACKMAN (Rochester) writes: Probably many other practitioners come across cases of cancer affecting members of the same family, but the following cases in two families particularly are worthy of note:

| Family 1.               |     |     |   |
|-------------------------|-----|-----|---|
| Edward B., 76           | ... | ... | Cancer of stomach.                        |
| Emma, 74                | ... | ... | Ditto.                                    |
| Emma, 45 (her daughter) | ... | ... | Cancer of breast.                         |
| Charles, 56             | ... | ... | Cancer of liver.                          |
| James, 52               | ... | ... | Cancer of bowel.                          |
| Family 2.               |     |     |   |
| Mrs. B., 76             | ... | ... | Cancer of breast.                         |
| Mrs. P., 73             | ... | ... | Cancer of bowel.                          |
| Mr. P., 74              | ... | ... | Cancer of right cheek, mouth, and throat. |
| Mrs. W., 72             | ... | ... | Cancer of breast.                         |
| Mr. P., 55              | ... | ... | Cancer of right eye.                      |

In addition, I have records of mother and two daughters—all cancer of stomach; two sisters—cancer of uterus; also brother and sister—cancer of liver.

## HERPES ZOSTER AND VARICELLA.

DR. W. P. LE FEUVRE (M.O.H. Knysna, South Africa) writes: With reference to the case reported by Drs. L. E. Green de Woolfson and W. H. Smith in the JOURNAL of May 29th (p. 902), may I point out that the appearance of the herpetic and varicellar eruptions in an infant of 8 months is probably a record as regards age only, as numerous similar cases have been reported in the JOURNAL and elsewhere, both in children and adults. An early case is to be found (at first mistaken for small-pox) in the Sydenham Society's *Transactions* for 1867. A recent case was also described in this JOURNAL on March 6th (female, aged 42), and in children aged 4 and 7 years respectively on December 6th, 1924, and August 22nd, 1925. The 8-months infant apparently inherited a very sensitive nervous system from her mother, as evidenced by the latter's attack of shingles three months previously, necessitating hospital treatment—an unusual event in the case of a comparatively young subject, such as I presume the mother to have been. As far as one can judge, it is this sensitiveness, either inherited or acquired, that decides what form the eruption shall take—herpetic, varicellar, or both—in those who have been in contact with either shingles or chicken-pox. The incubation stage seems to be practically the same in all reported cases. I am still wondering how long it will be before the two eruptions come to be recognized as part and parcel of one disease, which, as I suggested some years ago, might not unfitly be termed "varicella herpetica." In the case of a boy, aged 6 years, who came under my care about three years ago, the mother was intensely musical and highly strung, and the youngster seemed to inherit these same characteristics. After a short contact with chicken-pox he developed first an attack of shingles, necessitating morphine for the extreme pain and sleeplessness, and four days later (the usual interval) was covered with an ordinary chicken-pox rash. His elder sister, less nervous, was satisfied to take the disease in the shape of the varicellar eruption only.

## AN ANCIENT NEEDLE.

DR. G. VARIAN (Watford) writes to record the case of a spinster, aged 74, who consulted him for a large extravasation and ecchymosis over the lower third of Hunter's canal and the adductors. As she had a high blood pressure the local anæsthetic was applied to this and its attendant pathologic. Dr. Varian continues, "about a month later. She complained of pain under the area affected, and on applying some pressure to the deep tissues a sudden little cone of skin appeared, on the point of which I pricked my finger. I removed a needle, of a type which has not been seen or made in this country for many years. It is a hand-made black steel needle, with a roughly squared eye end and a simple hole punched through for the thread. My patient never saw such a needle before and has no memory of its painful entry. I suggest that she sat on her mother's needle in early childhood."

## ARSENIC IN APPLES.

In his annual report Dr. W. J. Howarth, medical officer of health for the City of London, states the results of investigations into the presence of arsenic in apples brought from America. The only apples with indications of arsenical deposits were "Jonathans"; it was with apples from America corresponding to these that prosecution was instituted in another area. The fruit contained 1-700 grain of arsenious oxide per pound. As the quantity of arsenic was so small Dr. Howarth did not consider it necessary to restrict the sale of these apples, but he considers that fruit should be exported entirely free from arsenic, since, if small quantities of poison are disregarded in one food, other poisonous substances, also in small quantities, might be added to other foods, and the aggregate consumed might be considerable.

For the convenience of residents in the London area a showroom has been opened by Messrs. Boulton and Paul, at 135-37, Queen Victoria Street, E.C., where specimens of their motor houses, shelters, etc., may be seen.

## VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 37, 38, 39, 42, and 43 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 40 and 41.

A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 162.

## MISTAKES IN ARTIFICIAL FEEDING OF INFANTS.

## Observations

ON

COMMON MISTAKES IN THE ARTIFICIAL  
FEEDING OF INFANTS.

BY

ERIC PRITCHARD, M.A., M.D. OXON., F.R.C.P. LOND.,  
MEDICAL DIRECTOR OF THE INFANTS HOSPITAL, LONDON.

It is common experience that we learn more from our mistakes than we do from our successes, but in no sense is this more true than in connexion with infant feeding. It is a disadvantage rather than a blessing, both for himself and his patients, when the young practitioner is successful in this department of his work at the threshold of his career, for in such circumstances he is apt to regard himself as an expert and an authority in a matter of which no man can become a complete master, even though he devote a long life to the subject. We learn more from our own mistakes than we do from those of others, and I offer no apology for making certain confessions of the mistakes which I have made myself during many years of practice, for although they may not be so helpful to others as they have been to myself, they may possibly assist others to avoid falling into the same traps.

During his novitiate the practitioner learns very little about the details of infant management; at least, in my day he learned very little until he married and had children of his own; on these he could experiment and learn at first hand from bitter experience the full degree of his own incompetency. The worst thing that can happen to such a tiro is to beget a child of such irrepressible vitality that his sins of commission or omission remain unrevealed. I fed my first child, with the most perfect results, on milk carefully modified on a percentage basis by the Walker Gordon Laboratories. Exactly the same feeding had fatal consequences in the case of my second child—through no fault of the laboratories, but solely owing to a study competence—and it was that never-to-be-forgotten experience that determined me to devote my life to the future. Of the means of obviating such disasters in the other day, I came across a somewhat analogous case in respect of when a young practitioner asked my advice in exactly a desperately wasted baby which had been fed in exactly the same method as two of his own infants, which, according to his account, had fared extremely well. The food employed was a baked flour sold under a particularly attractive and high-sounding title. As he was leaving the house he said, "By the by, do you happen to know what this food really is?" When I told him that it consisted of nothing more than baked flour sold at a fancy price he seemed greatly disturbed, and told me he always understood it was some artificial digestant.

It often takes a long time to learn the insistent truth that what is one man's food is another man's poison, and want of appreciation of this fundamental principle in infant feeding frequently leads the young practitioner to hold in high regard for general use certain peculiarly constituted preparations which have proved of signal service in the treatment of pathological conditions. For instance, infants who have been fed on rich nursery milk, with an excessive percentage of cream, and who have in consequence acquired intolerance of fat, may be fed quite rationally for a time on a malted milk which contains practically no fat but a very high percentage of malt sugar. The inexperienced person who is ignorant of the exact chemical composition of such and similar foods, and who does not realize the physiological necessity of balance, may very easily draw faulty inferences from his observations, and regard foods which are really suitable only for pathological conditions as physiological foods applicable for normal conditions. A great many of the ill balanced proprietary foods which are still on the market owe their reputation and popularity to causes of this kind.

Owing to recent discoveries of biochemists, and to elaborate and carefully conducted feeding experiments on animals, often carried out on whole colonies of quickly

breeding varieties, we now know a great deal more about the essential requirements of animals and, by inference, the ultimate results of incorrectly balanced dietaries in the case of human beings, than we knew a few years ago—in fact, a great deal more than we ever learned or could learn from the observations of feeding experiments carried out on human individuals for very short periods and practically never for more than one generation. We are very apt to judge of the suitability, or the reverse, of certain methods of feeding or of particular foods by the immediate and not by their ultimate results. The human organism has such wonderful reserve powers, such remarkable powers of adaptation and compensation, that the full consequences of a defective dietary may remain latent or unobserved, not only during the greater part of infancy, but possibly during a whole lifetime. This has been clearly shown in the case of animals experimentally fed, and it may be read in the epidemiological histories of whole nations who have perpetuated the same faulty dietetic customs for several generations. If infants were capable of holding up the danger signal of distress immediately they were improperly fed, their feeding would soon be placed on a more satisfactory basis. But from the analogy of the feeding of lower animals we now have so complete a knowledge of the nutritional requirements of the human body, both from the point of view of development and maintenance, that, even in the absence of symptoms which attract attention, it is easy to predict what will be the ultimate consequence of any particular line of feeding. Even in such widely studied matters as the vitamin deficiency diseases we have no means of diagnosing their first beginnings except from the history of the feeding. We know, for instance, that the symptoms of scurvy in infants do not manifest themselves for some three or four months after the commencement of a vitamin-free diet. This is the reason for the astonishing practice, which is so prevalent in this country, of delaying the administration of antiscorbutics until after the third month of life. The argument is so plausible: infants under three months of age do not have scurvy; therefore they do not require antiscorbutics. If there is one period more than another when infants, and especially premature infants, stand in need of this and other accessory factors in their diet, it is during the first three months of life.

Another example of the delayed effects of faulty balance is the ultimate development of hyperchlorhydria in infants fed on whole milk, or unmodified dried milks; for a while they appear to thrive and do well, but if they can survive this monstrous liberty with their digestive and metabolic functions, they must, on grounds which are now thoroughly well understood, acquire an immense capacity for secreting hydrochloric acid, and they either die in an attempt to produce enough acid to overcome this buffer influence of the caseinogen, or suffer at a later date from the success of their early adaptability.

A considerable number of the dietetic misconceptions under which humanity is still groaning have their origin in the fallacy enunciated by the older physiologists that food subserves in the animal body the identical function that fuel subserves in the mechanical engine—namely, that of a potential source of kinetic energy and heat. The belief that the be-all and end-all of dietetics was to balance the intake and output by a careful adjustment of caloric values has put back the clock of scientific feeding by more hours than one cares to contemplate. It is perhaps hardly fair to describe the pioneer work of some of our greatest physiologists as wrong; their views and observations in these matters were true as far as they went; but they did not cover the whole ground—were in fact half truths, as the next generation of physiologists pointed out when they discovered the significance of balance, and when the present generation of physiologists further demonstrated the part which the accessory factors play in the utilization and combustion of the simple fuel foods.

The essential difference between the fuel required by a mechanical engine and the food which is shovelled into the furnaces of the animal organism is that, while the former should only contain sources of energy, food must contain either the ready prepared elements or the crude material out of which the latter can be elaborated for such

purposes as those of cleaning the machine, for lubricating it, for controlling its carburetors, its sparkers, its dynamos, its exhaust, and all the other elaborate mechanisms of the most complicated and perfect automatic engine. The mere supply of fuel to such an engine, no matter how well such fuel is mixed or balanced, is only a very small part of the duty of the stoker. And this is where the older physiologists, as well as the most modern percentage feeders, have gone so seriously astray; they have given infinite attention to the exact percentage relationships of the fats, the proteins, and the carbohydrates, and they have almost completely neglected the still more important duty—that of making provision for the control and running of the machine by providing the required accessory factors.

There are in milk, which one must regard as a complete and perfect food, three different classes of fuel, and there are also at least thirty-seven other elements or proximate principles, each one of which subserves some nutritional purpose which is of equal or perhaps greater importance, but is in no sense a fuel. We cannot believe that Nature, in her infinite wisdom, is so prodigal as to supply anything that is redundant or unnecessary, or so careless as to omit any essential in the food she supplies for the nourishment of the young; it is, indeed, implicit in the survival of the race that such must not be the case with respect to human milk. It is true that at present we do not know exactly how much of any of the vitamins or of the other accessory factors, such as iodine, or lecithin, or cholesterol, or iron, any baby or adult requires, but we are surely justified in believing that the representation of each in breast milk is of about the correct standard for the infant, as in the milk of other mammals their representation is correct for their respective progeny. It is possible that the representation in cow's milk is approximately the same with respect to most of them as it is in human milk, and if so the human infant ought to thrive when a given volume of cow's milk is substituted for a given volume of breast milk. But early experience taught the older physicians that whole cow's milk could not be digested like whole breast milk, and therefore cow's milk was diluted with one, two, or three parts of water, in order that the great excess of the indigestible constituent—that is, the caseinogen—might be watered down to the point of tolerance. A later school, recognizing that the infant suffered from the coequal dilution of the fat and of the sugar, added these to make up the deficit or supply the special requirements. A later generation recognized the need for making good the deficiencies of the vitamins and perhaps one or two other essential factors; but how many at the present time, when providing for these adjustments, think of the deficits of iron and iodine and perhaps a dozen other essential factors in nutrition? This, to my mind, is an explanation of some of the failures of feeding with cow's milk modifications, and of some of the apparent successes of whole-milk feeding, which on other counts has little to commend it.

Many years ago that great chemist Baron von Liebig enunciated his law of "the minimum," a law which to-day, in view of our more accurate knowledge of nutritional requirements, has more cogency than at the time of its formulation. This law is that the maximum degree of nutrition possible under any system of feeding or with any diet is determined by its greatest fault, and not by its greatest virtue. For instance, if we allow that some forty different constituents are requisite for a complete dietary, and that the faulty representation of any one of them in any particular diet allows only of a 50 per cent. realization of the possible maximum of nutrition, the net result will be only a 50 per cent. success, no matter what degree of perfection is attained by the thirty-nine other elements. It is quite easy to visualize such a hypothetical result in the case of such a default as that of a vitamin, but it is less easy to realize that the same catastrophe will follow faults in the supply of such little-considered elements as iodine, chlorine, fluorine, and many other constituents of diet which at the present time receive little consideration.

I have purposely included in the category of essential elements certain mineral constituents, for although it is well recognized by plant physiologists that for success in

agriculture or floriculture the supply of a considerable number of mineral elements is absolutely necessary, the same need is not by any means realized by those who concern themselves with the nutrition of developing human beings.

Soils which are deficient in certain mineral elements will not produce the maximum, or even a good crop, until the required balance is redressed. In animal nutrition there is not only a comparable need of many different minerals, but a far more comprehensive one. Owing to the fact, however, that when any form of milk diet is employed in the feeding of infants there is never a complete absence, but only a relative shortage, of any required element, defects in this respect never make themselves obtrusive. In this connexion I would observe that there is practically always a great deficiency of iron in the artificial feeding of infants when cow's milk dilutions are employed as the basis of their diet, and further, that there is often a grave deficiency of iodine, potassium, and ionic calcium. I do not propose to discuss this point further than to indicate that any one single defect in this respect will, in accordance with Liebig's law of the minimum, reduce the standard of nutrition to a degree which is proportional to the default.

Mistakes in respect of such niceties of balance are to a large extent excusable, for the reason that, owing to want of exact knowledge, no clearly defined rules are available with regard to the quantitative or qualitative requirements; but there should be no excuse for gross mistakes with respect to the balance of the fuel elements or their calorie value, because we have certain general indications for their adjustment. I do not want to flog a dead horse, but I cannot help making some passing comment on the argument which I constantly hear—namely, that in whole-milk feeding the large excess of nitrogenous elements is justified on the ground that such excess is required because, owing to the indigestible character of its contained caseinogen, the infant cannot assimilate an adequate supply unless it is proffered in massive amount. It is to my mind a strange argument to contend that, because a particular element is incapable of digestion, it should be supplied in excessive amount. It might be logical to suggest that it should be given in a more digestible form or replaced by some more digestible equivalent, but to maintain that it should be given in larger amount requires a good deal of justification.

As there is an optimum balance with respect to the combination of the energy-affording elements of an infant's food—namely, with respect to the combination of the proteins, fats, and carbohydrates—so also is there an optimum as regards their united calorie value. The tolerance of the animal organism in this respect is admittedly great, but any serious default, either in the direction of excess or inadequacy, must interfere with the attainment of that optimum result at which we should aim.

I do not claim that the age, or weight, or sitting height, or any other single factor taken by itself, will give us an accurate measure of the calorie requirements of any particular infant, but whatever means we may use to arrive at an approximate estimate of the energy value of the food required, we ought at least to be consistent, and not vary the amount when we find it necessary to change some unsatisfactory combination of foods for one we believe to be better. Inconsistencies of this character, in changing from one food to another, are my common experience; the following instance may illustrate my point.

An infant was ordered a milk mixture of a certain definite composition, and of a value of 600 calories; when this did not answer a diet of condensed milk was substituted of a calorie value of 150. Another infant was directed to be fed on a dilution of half cream ("cow and gate") with a calorie value of 400. When this method of feeding was found to be a failure, a diet of *almata* was substituted for it with a calorie value of 800. The law of the conservation of energy is either applicable or not in the feeding of infants; if it is applicable such transgressions must inevitably bring their Nemesis. I may add that these two dietetic mistakes were not made by inexperienced practitioners, but were the directions given at two children's hospitals in London, and are of the kind

SEPT. 25, 1926]

## THE SCHICK TEST.

of which I have made many myself in my unregenerate days, before I based my estimation of quantities on calorie values.

Speaking of quantities, I may be allowed to draw attention to the serious mistakes to which the employment of such indeterminate measures as teaspoonfuls and tablespoonfuls may lead the unwary. An ordinary tablespoon has a fluid capacity of about one ounce, and not half an ounce as is generally supposed, while the actual weight of a level tablespoonful of such a dry food as glaxo or "cow and gate" milk is about three drachms. The fluid capacity of an ordinary teaspoon is seldom less than a drachm and a half, while its capacity for a dry powder is little more than half a drachm. From this it is obvious that serious mistakes may arise when more accurate means of measurement are not employed. As an example of the sort of error into which the employment of such inaccurate measures may lead us I may quote the following instance:

An infant was brought to the Infants Hospital with serious symptoms of nutritional failure; it had been fed on condensed milk, and I was anxious to know the exact quantity which had been given it. On inquiry I was told that it had been given one teaspoonful in three ounces of water for six feeds, giving a total quantity of six teaspoonfuls in the twenty-four hours, with a face value of 80 calories in the twenty-four hours. The deficiency in food value seemed to me to be so great that I attempted to check the estimate by asking how long a tin of condensed milk lasted. The mother told me that she used, on an average, three tins (1 lb. by weight each) every week. Reckoning on this basis I argued that the infant was daily supplied with about 7 ounces of condensed milk with a value of about 700 calories. The discrepancy between the 80 calories as estimated in teaspoonfuls and the actual and true quantity as estimated in milk purchased and used shows unquestionably the fallibility of the domestic measure. I could multiply pitfalls of a similar nature almost indefinitely, but perhaps I have said enough. I submit, however, that recent development in our knowledge of nutrition has not simplified the feeding of babies, but has rendered it an infinitely more responsible and difficult task.

## THE SCHICK TEST: A SCHEME FOR ACTIVE IMMUNIZATION AGAINST DIPHTHERIA IN PUBLIC HEALTH PRACTICE. BY ERIC DONALDSON, M.D. CANTAB., ASSISTANT MEDICAL OFFICER, COUNTY OF SURREY.

ALTHOUGH most medical men are familiar with the Schick test, yet for the benefit of those who have not had practical experience of it the following explanatory note may be of assistance.

The Schick test is a definite quantitative test to demonstrate the amount of diphtheria antitoxin in any given person. Those patients in whom the test proves to be positive have only a small amount of antitoxin, and are therefore liable to contract diphtheria, whereas those in whom the result is negative have sufficient antitoxin to ward off the disease. Those who are positive to the test—in other words, those who are susceptible to diphtheria—can be rendered immune by the injection of a prophylactic mixture.

The following figures show that there is sufficient evidence of the efficacy of these procedures to warrant their more extensive use in combating the disease.

In New York City for the ten years preceding the introduction of Schick testing and immunization, the average number of deaths from diphtheria was 1,337; in 1919 the number of deaths was 1,239. Since 1919, when modern methods were first introduced on a large scale, the number has fallen to 663. Similarly, in Chicago, there has been a fall from an average of 797 deaths to 239 deaths. It has also been shown that in 23 representative American cities the death rate from diphtheria has fallen an average of 10.5 per cent. per annum.<sup>1</sup>

In this country about 22,000 of the population have been Schick tested, and about 4,000 have been immunized. A large

proportion of these cases are the children and staffs in institutions.<sup>2</sup> On one occasion reported, the inmates in an institution remained free from diphtheria although exposed to infection at school and in constant contact with children amongst whom the epidemic continued.<sup>3</sup> Dr. E. H. R. Harries of Birmingham has succeeded in entirely eliminating diphtheria among the nursing staff of the Birmingham fever hospitals.<sup>4</sup> It has also been shown that in other fever hospitals where nurses have been adequately protected by immunization, the incidence of diphtheria among them has dropped practically to zero, whereas no such drop has occurred where nurses are not thus protected.

In the summer of 1925 I immunized the children susceptible to diphtheria in an orphanage in Surrey. Within the previous eighteen months there had been two outbreaks of the disease in the institution and among the children of the elementary school attended by the orphans. No case of diphtheria has occurred in the orphanage since this work was carried out, although a number of cases have occurred in the school. During the summer holidays in 1925 two of the immunized children slept for three nights in the same bed as a child who was incubating diphtheria, but neither of them contracted the disease.

In a training ship where diphtheria had been endemic the boys were tested, and those found to be positive were immunized. As long as all the new entrants were immunized (where this was indicated) no case of diphtheria occurred, although there were many profuse carriers of virulent diphtheria bacilli.

These are a few of the results obtained in this country, but up to the present Schick testing and immunization have only been carried out on a small scale, in comparison with what has been done in the United States.

So far as I am aware there have been no failures—that is to say, genuine diphtheria has never occurred in a Schick-negative person. A certain number of failures have been reported, but it has been found on careful scientific investigation that these are not true cases of diphtheria; or it has been found that the Schick test has been improperly carried out. To establish a diagnosis of diphtheria in a Schick-negative person three conditions must be satisfied—namely:

1. The clinical picture must be typical.
2. Virulent Klebs-Loeffler bacilli—that is, as tested in a guinea-pig—must be present in the throat or nose.
3. A sample of blood taken before a therapeutic dose of antitoxin has been given must show that there is sufficient natural antitoxin to ward off an ordinary attack of diphtheria.

**Immunity.**  
Immunity may be active or passive. The process by which the production of antitoxin in the tissues of an individual is stimulated, whether artificially or otherwise, is called active immunization. The immunity produced by this process is much more lasting than the immunity produced by the introduction of artificially prepared antitoxin into the circulation. The former lasts for years, and potentially for life; the latter lasts only for a short time, generally three to eight weeks.<sup>5</sup>

Active immunity is produced by the injection, at weekly intervals, of 1 c.cm. doses of diphtheria prophylactic. Thus preparation consists of toxoid (prepared by treating diphtheria toxin with formalin) and antitoxin. Three or four weekly injections are usually sufficient to produce immunity, but some individuals require further injections if they are found to be Schick-positive three months after treatment.

### Defects of Present System of Combating Diphtheria.

It may be as well to point out here the defects of some of the older methods of preventing the spread of diphtheria. The two most widely used of these methods are:

1. The swabbing of all contacts, and the isolation of those giving positive cultures, those with negative cultures remaining free.
2. The injection of a prophylactic dose of antitoxin (500 to 1,000 units) to all contacts.

As regards the first of these procedures, six types of subject may be met with, from the point of view of their immunity and infectiousness,<sup>6</sup> and may be set out thus:

- A. Schick-positive, swab negative.
- B. Schick-positive, swab positive, bacilli avirulent.
- C. Schick-positive, swab positive, bacilli virulent.
- D. Schick-negative, swab negative.
- E. Schick-negative, swab positive, bacilli avirulent.
- F. Schick-negative, swab positive, bacilli virulent.

Among those with "positive swabs" who are isolated (probably together) there may be a number from classes B, C, E, and F. Class C is obviously those who are incubating diphtheria, and will develop the disease in a day or two. Class E is not susceptible to diphtheria, and, since their bacilli are avirulent, it is immaterial whether they are isolated or not. But the juxtaposition of Class F, the non-susceptible carriers of virulent bacilli—among whom there may be profuse carriers—and Class B, the susceptible subjects, involves danger, probably acute danger, to the latter. On the other hand, if the modern method about to be described is employed, such a juxtaposition will not occur, because the susceptibles and non-susceptibles will be separated.

As regards the second of these procedures—that is, the injection of prophylactic doses of antitoxin—there are two distinct disadvantages: First, such an injection may render the person injected serum-sensitive, and so complicate treatment in the event of a subsequent attack of diphtheria. Secondly, the immunity conferred is of a comparatively short duration. This was proved in the case of one institution observed by Dr. Okell, where an epidemic was checked by prophylactic doses of antitoxin, but cases occurred again within a few weeks. I came across two cases at the orphanage mentioned above, where therapeutic doses of antitoxin had been given, and within eight weeks they were non-immune. On the other hand, the experience of Park and his colleagues in New York, and of workers in this country, shows that the active immunity produced by the injection of toxoid antitoxin mixtures lasts for some years in a great majority of cases, and probably for life.

Another defect in the present system is that it is not sufficiently realized that the diagnosis of the true Klebs-Loeffler bacillus from its microscopic appearances is extremely difficult and in itself insufficient. There are certain forms, indistinguishable from it, which are quite harmless and do not produce diphtheria. This, therefore, involves a risk that people who have not got diphtheria are segregated with others who have; and, on the other hand, Schick-positive carriers of harmless diphtheroid organisms may be isolated, possibly for months, as true diphtheria carriers.

When a positive report is obtained it is advisable to have the cultures tested to see if they will produce diphtheria in guinea-pigs. Where the modern methods of Schick testing and active immunization are being applied it is important that medical men should have the above facts clearly in mind, otherwise confusion is likely to arise.

#### *Proposed Scheme for Combating Diphtheria on a National Scale.*

The practical utilization of modern methods for the control of diphtheria consists in a routine application of Schick testing and active immunization in interepidemic times; and the employment of these methods to gain control during an epidemic, which will be referred to as "emergency application." This will now be discussed under the following headings:

1. Routine application: (a) in resident institutions; (b) in special clinics; (c) in day schools; (d) for those in attendance on cases of diphtheria.
2. Emergency applications: (a) in resident institutions; (b) apart from resident institutions.

#### *Routine Application.*

**Resident Institutions.**—Diphtheria is conspicuously an "institutional" disease, and it is in institutions that modern methods can best be applied. The application of the Schick test is a simple matter in the hands of those trained to its use. One operator, with a trained assistant and efficient marshalling of those to be tested, can easily test fifty cases in an hour. At the end of seven days the positive cases can be separated from the negative, and active immunization can be commenced. With efficient organization the injection of toxin-antitoxin is a very simple matter, and takes up very little time.

**Special Clinics.**—At first sight it would seem to be a simple matter to have children under 5 years of age tested and immunized at child welfare centres, but if

children were sent in large numbers this would interfere seriously with the ordinary work of the centres. Schick testing and immunization have been carried out at welfare centres, but I am of opinion that it would be simpler to follow the plan adopted at Fraserburgh and conduct special clinics at suitable intervals. By means of those clinics it should be possible to immunize the majority of children under school age. This is most important because, as pointed out by Park and Zingher, the mortality is greater among these than among older children; also there is a risk of their contracting diphtheria when they enter school.

**Day Schools.**—Schick testing and active immunization can be carried out in the schools with the co-operation of the teaching staff. The interference with school work need not be great. If the marshalling is properly arranged the interference is scarcely greater than at an average routine medical inspection. Moreover, once a school has been tested and the positive cases have been immunized it is only necessary to deal with fresh entrants. If younger children are being immunized at special clinics before entering school, the number to be dealt with in the schools will rapidly diminish. As many children as possible should be immunized before entering school, otherwise there is some risk of their contracting diphtheria while awaiting immunization.

#### *Emergency Work.*

A method of rapidly getting control of epidemics in institutions has been devised.<sup>6</sup> This method is applied in the following manner:

1. Schick test all persons in the institution.
2. If possible swab all persons, throat and nose.
3. In twenty-four to forty-eight hours, isolate all Schick-negative reactors.
4. For a few days see twice daily all positive reactors (to detect any who may develop the disease).
5. Test for virulence all positive swabs from Schick-negative reactors, release "avirulent," but rigidly isolate all "virulent carriers."
6. Begin at once to immunize all Schick-positive reactors.

The originators state that this plan depends upon the following "propositions," which are sufficiently true for the effective working out of the plan:

1. Schick-negative reactors are not susceptible to diphtheria.
2. Schick-positive reactors are susceptible to diphtheria.
3. Schick-positive reactors never harbour virulent bacilli detectable by ordinary swab culture methods unless they are suffering from or are incubating the disease.
4. Carriers of virulent bacilli are immune and are always Schick-negative reactors.
5. "Avirulent" bacilli do not cause diphtheria, and therefore "avirulent" carriers are of no importance to the public health authorities.
6. One efficient swabbing of a population gives a sufficient working knowledge of the location of infection—that is, all profuse, and therefore dangerous, carriers will be detected.

Independently of the originators of this plan, Dr. E. H. R. Harries worked out a similar scheme to control outbreaks of diphtheria in fever hospitals, and found it very effective.

Apart from resident institutions the scheme would be much more difficult to work, but if the organization were good there seems to be no insurmountable obstacle. The main difficulties would be that the whole population possibly would not be tested, and dangerous carriers might go undetected; and that to separate negatives from positives outside institutions would not be easy.

As regards the first difficulty, if the local practitioners understood the scheme properly their influence would help very materially to ensure that the vast majority would be tested. Moreover, in the presence of an epidemic objections would be far less numerous than at other times. Much could be done, too, by carefully worded explanations.

As regards the second difficulty, assuming that nearly all the population were Schick tested and swabbed, the dangerous carriers could be removed to the isolation hospital, which would not be unnecessarily filled with Schick-positive carriers of harmless diphtheroids.

For emergency work in rural districts it would be necessary for the county medical officer of health to have on his staff a number of medical officers trained in the use

of modern methods of diphtheria control, and health visitors trained to assist them. When an outbreak occurred these officers could be sent to the area concerned and could then proceed to carry out the necessary work.

It should not be difficult to organize "mobile units" of this description. Obviously these officers would need to be tested, and if necessary immunized. All those who come in contact with diphtheria should be immune. There is no excuse nowadays for nurses, or others who have the care of diphtheria patients or suspects, contracting the disease. At the present time the number of medical officers who understand modern methods of combating diphtheria is quite inadequate. Large numbers require to be trained. The technique is very easy, and experience in interpreting results does not take long to acquire.

No candidate should be allowed to graduate in State medicine unless he or she is proficient in applying the Schick test, and understands the fundamental facts of immunity. Local authorities should insist on as many of their medical officers as possible being trained for this work.

In order to avoid haphazard and inefficient working and to co-ordinate the work throughout the country, certain standards would have to be laid down and an advisory committee would have to be appointed, consisting of experienced immunologists who could ensure that, although details of administration would obviously vary locally, fundamental points would not. This committee might also act as an investigation department, to examine any reported "failure" of the methods and to present any points of interest that might arise to research workers. Such a department could prevent the methods from falling into discredit through uninformed criticism, and by keeping the public informed would be able to frustrate the efforts of those misguided people who are striving to abolish the experimental method on which every advance in medical science depends. They would also save a good deal of time for research workers by relieving them of the trouble of extracting information on subjects of interest to them from a mass of irrelevant matter.

It would be an advantage to have at selected centres a number of reliable laboratories where the workers would be capable of making a scientific bacteriological diagnosis of diphtheria, and who would be able to perform properly controlled virulence tests, and to titrate antitoxin in blood samples. This need not be a matter of great expense, as existing laboratories could be utilized if brought up to date. It seems probable that in the near future (as pointed out by the BRITISH MEDICAL JOURNAL for February 13th, 1926, p. 295) the "diphtheria simultaneous prophylactic and indicating mixture" will simplify and shorten the whole process of testing and immunization.

#### Conclusions.

1. That the Schick test has been proved to be a reliable test for susceptibility or non-susceptibility to diphtheria, and that the immunity conferred by injecting toxin-antitoxin mixtures is lasting. My own experience in testing and immunizing an institution agrees with the experience of others.

2. That with careful preparation of the public by fully explaining the facts about diphtheria, and with the co-operation of the general practitioners, modern methods of diphtheria prevention could be employed on a national scale; and that a campaign on these lines, resolutely carried out, would result in the reduction of diphtheria incidence to negligible proportions. If properly organized the cost of such a campaign would be extremely small, compared with the enormous cost of treating thousands of cases annually. It is interesting to note that the outbreak at an orphanage in Surrey, already referred to, involved an expenditure of £500. Schick testing and active immunization (with swabbing of Schick-negative cases) cost about £25—certainly not more than £30—and the cost of testing the new-comers each year will be negligible.

I wish to express my indebtedness to Dr. Joseph Cates, county medical officer of health for Surrey, for entrusting me with the work of diphtheria prevention by modern methods, and for kindly permitting me to make use of the records of work done in the county; also to Dr. R. A. O'Brien and his colleagues of the

Wellcome Physiological Research Laboratories, Dr. C. C. Okell and Dr. H. J. Parish, and Mr. A. T. Glenn, for the assistance, advice, and instruction which they have so generously given, and for carrying out antitoxin titrations and other laboratory work.

## A CASE OF CHLOROMA IN A CHILD.

BY  
FREDERICK M. B. ALLEN, M.D., M.R.C.P. LOND.,  
HONORARY ASSISTANT PHYSICIAN, BELFAST HOSPITAL FOR SICK  
CHILDREN; MEDICAL REGISTRAR, ROYAL VICTORIA  
HOSPITAL, BELFAST.

CASES of chloroma in children are considered sufficiently rare to warrant the following notes of a case.

A girl, aged 4½ years, was referred to me for investigation as to the cause of pallor, weakness, and cough. On January 28th she was admitted to the Belfast Hospital for Sick Children under Dr. M. Brico Smyth, to whom I am indebted for permission to publish these notes.

She was well nourished, but pale, and had a certain amount of "fullness" in the upper eyelids suggesting proptosis; right-sided facial paralysis, probably due to haemorrhage into the facial canal, was present. The lungs presented no definite physical signs other than scattered rhonchi. The heart was normal. The spleen was easily palpable, reaching for its position. A blood count showed red cells 1,480,000 and white cells 41,000.

The film showed myeloblasts and numerous normoblasts, and numbered 19th the red cells numbered 1,450,000, the white cells 56,000. Film as before. On February 25th the red cells numbered 1,430,000 and white cells 81,000. Haemoglobin 24 per cent. The film showed a large number of normoblasts and various types of white cells. Two days later it was noticed that the lymph glands in the size of the spleen. A left subconjunctival obvious change was also noted. The next day the left eyeball was haemorrhage was also noted.

On March 3rd the fundus oculi revealed numerous haemorrhages. The eyeball was protruded further and further, and at the end of a week was almost outside the orbit. On March 11th there was a crop of petechiae on the arms and some purpuric spots elsewhere. The spleen was definitely larger. Death occurred that evening. Unfortunately the parents would not permit a post-mortem examination, but by a partial enucleation of the left eyeball a portion of the tumour was obtained. It was distinctly green in colour, and remained so for more than twenty-four hours in formalin.

**Microscopical Examination.**  
On section the tumour was seen to be lympho-sarcomatous in form, and it infiltrated the surrounding fat. It showed numerous lymph spaces scattered throughout. The stroma, while not abundant, was better developed than in a round-celled sarcoma and in places showed masses stained pink by van Gieson. The cells were mainly of the large round-cell type; there were several multinuclear cells, the nuclei being grouped together in the centre. Several mitotic figures were seen.

#### Summary.

1. A case of chloroma in a child of 4½ years is recorded.
2. The chief subject of complaint by the parents was pallor, weakness, and cough.
3. When first seen there was a right-sided facial paralysis, enlarged spleen, and the blood picture of a fairly acute myeloblastic leukaemia.
4. With the onset of haemorrhages, purpura, and rapid growth of the tumours, deterioration was rapid and death quickly supervened.
5. The colour of the piece of tumour removed was green. Recognizing that in many cases all the clinical and haematological criteria of chloroma may be present and yet the tumours be white, this would appear to be a genuine case of the condition.

\* Dr. A. Piney of the Institute of Pathology, Charing Cross Hospital, very kindly made this count. Dr. J. T. Lewis, honorary bacteriologist to the Belfast Hospital for Sick Children, was responsible for the others. I am much indebted to them both for their interest and help.

## THE ABDOMINAL CRISES OF PERNICIOUS ANAEMIA.

BY

HAMILTON BAILEY, F.R.C.S. Eng.,  
SURGEON, DUDLEY ROAD HOSPITAL, BIRMINGHAM.

Much attention has been directed to the simulation of the gastric crises of tabes by perforated gastric ulcer. At the present time the mistake of operating upon a patient with a tabetic gastric crisis is rare. During six years' continuous association with emergency surgery in widely separated clinics I have not come across a single example of this error, which has been eliminated by the routine practice of testing the reaction of the pupil and for the presence of the knee-jerk in every suspected case of gastroduodenal perforation.

The object of this note is to call attention to another medical condition which simulates very closely an acute abdominal catastrophe.

The later stages of pernicious anaemia are occasionally complicated with what may be termed abdominal crises. They resemble so closely one of the recognized acute abdominal conditions, such as perforated gastric ulcer or acute pancreatitis, that when confronted with one for the first time even the most conscientious surgeon may be trapped. The ghastly pallor, especially in artificial light, is mistaken for that of profound shock or internal haemorrhage, and when this picture is combined with a history of sudden agonizing abdominal pain and vomiting, and is accompanied by abdominal rigidity, the difficulty in diagnosis is occasionally almost insurmountable, unless, of course, we are in possession of the knowledge that the patient is the subject of an aplastic anaemia. The explanation of the sudden attacks of abdominal pain is fairly clear. During the katabolism of large numbers of erythrocytes the liver is called upon to excrete a prodigious amount of bile pigments. These pigments are too concentrated to be held in solution, and are precipitated in the form of "bile mud," which gives rise to severe biliary colic. Furthermore, the subjects of these crises, being worn out by a long illness and an impoverished blood supply, react very strongly to the painful stimuli. This theory is supported by the following cases, in one of which I performed laparotomy. The gall bladder was enormously distended, and when opened was found to contain thick, black "biliary mud."

## CASE I.

A Jew, aged 55, was admitted to the London Hospital on October 17th, 1922, at 2.30 a.m., as an "acute abdomen." He spoke no English, and the history was translated by a relative, who said that the patient was seized with sudden very acute abdominal pain seven hours previously. The pain was at first in the epigastrium, but later became general. He had vomited several times. As far as could be gathered the patient had previously been quite well, except for indigestion. The patient was exceedingly pale, and obviously in great pain. The abdomen did not move freely with respiration, and there was board-like general rigidity and tenderness, especially marked in the epigastrium and right hypochondrium. The liver, spleen, and kidneys could not be felt. The rectal examination and examination of urine were negative. The heart and lungs were clear. A diagnosis of perforated gastric ulcer was made, and laparotomy performed. The only abnormality found was a very distended gall bladder. By cholecystostomy a large quantity of biliary mud was evacuated. Three days later the patient became comatose, and died shortly afterwards. It was at this time ascertained that he had been in hospital one year previously with advanced pernicious anaemia.

## CASE II.

A woman, aged 58, was admitted to Dudley Road Hospital on January 25th, 1926, with a history extending over two years of frequent attacks of acute abdominal pain. The pain was always most marked in the left hypochondrium and passed through to the back. The present attack began four hours before admission, and was considerably more severe than any of the previous ones; the patient had vomited. On examination in artificial light she appeared to be somewhat jaundiced. The tongue showed evidence of superficial glossitis. There was general abdominal tenderness and slight upper abdominal rigidity. The spleen and liver were enlarged, and the latter distinctly tender. A diagnosis of gall

stone colic was made. Next morning it was noticed that the patient was not jaundiced in the ordinary meaning of the term, but was of a bright lemon tinge. A colour index was immediately taken, and gave typical reading for pernicious anaemia. She was transferred to the medical side, where this diagnosis was confirmed.

## THE TREATMENT OF VARICOSE VEINS BY INJECTION.

BY

A. H. DOUTHWAITE, M.D. Lond.

THE necessity for an efficient non-surgical treatment of varicose veins is emphasized by the ever-increasing number of advertisements of quack remedies in the press. The standard works on surgery affirm that, short of operation, the only treatment lies in mechanical support. As the result of two years' experience in the production of thrombosis in varicose veins, I am convinced that this line of treatment is superior to excision.

The procedure originally suggested by Geneyrier has been followed throughout. The solution used is composed of quinine hydrochloride 4 grams, urethane 2 grams, in distilled water 30 c.cm. A pneumatic tourniquet is applied with moderate pressure above the line of vein to be dealt with and 1/4 c.cm. of the solution injected into the lumen through a fine hypodermic needle. Perivenous administration is usually unnecessary; it is not, however, contraindicated, as the resultant inflammation is not severe, provided only a few minims are introduced outside the vein. The puncture is sealed with collodion, which may be removed the same night, and the injection repeated about two inches further up the vein. It is wiser not to introduce more than 2 c.cm. at one sitting.

The amount of pain accompanying the artificial thrombosis varies greatly in different patients, but is never sufficient to render walking impossible, and in the vast majority of cases little or no discomfort is experienced. All my patients have come to my consulting room and returned home in their usual manner. Several of them played tennis on the following day.

With very large varices the same areas may have to be injected two or three times. As a rule, however, one injection is sufficient for each two or three inches of vein treated. Of the 88 cases dealt with all have been completely successful, and no recurrences have as yet been observed. Initial swelling of the vein was not uncommon, but this soon subsided, and after a few weeks it may be felt as a nodular cord, causing no bulging on the surface of the leg unless it be situated over the subcutaneous surface of the tibia.

The relief of the lancinating pains or bursting sensations associated with the presence of varicose veins is very striking, and patches of eczema and ulcers often heal completely.

The cases treated were not selected. Many of them occurred in fat, middle-aged women, the veins extending up both legs into the thighs; yet they responded to treatment as readily as young adults. One lady was purposely avoiding a second pregnancy on account of her previous unhappy experience with varicose veins. Artificial thrombosis was produced, and she has since had a child with no mishap or recurrence of venous trouble. When commencing this treatment it is natural to be anxious lest embolism occur. The thrombosis appears, however, to be very firm and adherent, and has never given rise to embolic disturbances in injections which I have given—numbering more than a thousand.

The disability produced by varicose veins in this country is enormous. Thousands of otherwise healthy men were unable to take active part in the war on this account. Hundreds of men and women have to give up work to which they have been trained because it entails much standing. Furthermore, modern fashion decrees that the feminine leg shall be covered by thin silk only. The unsightly bulging of varices in this locality occasions the patient much distress. The advantages of this treatment over operation are obvious. Neither work nor pleasure is interfered with; neither preparation nor anaesthetic is required. If the treatment is carried out carefully and with reasonable dexterity no harmful effects will follow.

SECTION OF SURGERY.  
**British Medical Association.**  
**PROCEEDINGS OF SECTIONS AT THE ANNUAL MEETING, NOTTINGHAM, 1926.**

**SECTION OF SURGERY.**  
 Sir D'ARCY POWER, K.B.E., M.B., F.R.C.S., President.

**DISCUSSION ON  
 THE PLACE OF GASTRO-JEJUNOSTOMY IN  
 GASTRIC AND DUODENAL SURGERY.**

**OPENING PAPERS.**

**I.—HERBERT J. PATERSON, C.B.E., M.C., M.D., F.R.C.S.,**  
 Senior Surgeon, London Temperance Hospital.

There is probably no operation in surgery which has added more to the sum of human happiness than gastro-jejunostomy. Nevertheless every new discovery and every improvement has some attendant drawbacks, and the very success of gastro-jejunostomy has led to its performance without proper indications and in unsuitable cases, and so has brought upon the operation discredit which is totally undeserved.

There are some who consider gastro-jejunostomy an out-of-date, if not, indeed, an obsolete operation. More complicated but less rational measures have been designed to supersede it. It is time that a stand should be made against operations which are unnecessarily severe. Surely our duty is to get our patients well with the minimum of surgical interference and with the minimum of risk. My contention is that in the great majority of cases gastro-jejunostomy is a thoroughly satisfactory treatment both for gastric and duodenal ulcers, provided it is properly performed and that prolonged and efficient after-treatment is carried out.

Let us consider for a moment some of the arguments which are put forward in favour of partial gastrectomy. First, that it is a more certain cure. This has still to be proved. The operation of partial gastrectomy in the treatment of gastric ulcer is on trial, but the interval which has elapsed since it became a fashion is not long enough for us to judge as to the permanency of the cures. It is already certain that partial gastrectomy is not infallible. It is certain also that the mortality rate is higher. I am well aware that in the hands of a few experts the death rate may be little higher than that of gastro-jejunostomy; nevertheless few will be prepared to deny that partial gastrectomy is a more severe operation than gastro-jejunostomy, and that it is necessarily attended with a higher mortality. I agree with the opinion expressed by Sherren that the death rate from the large and complicated procedures devised to supplant gastro-jejunostomy at least approximates to the combined deaths and unsuccessful cases after gastro-jejunostomy. I shudder to contemplate the probable mortality rate if gastrectomy became the operation of choice in all cases by all operators.

Secondly, it is alleged that as some 60 per cent. of chronic ulcers show malignant changes, therefore all gastric ulcers should be removed. The teaching that all gastric ulcers should be removed is to become cancerous I regard as one of the most insidious heresies which have been invented to beguile and mislead the innocent surgeon. The cridence, if evidence it can be called, for this allegation is partly clinical and partly pathological, but is of the flimsiest description. It is indisputable that in a considerable number of cases of gastric cancer there is a history extending over years suggestive of gastric ulcer. Suggestion, however, is not proof, and a careful scrutiny of such histories leads to the suspicion that the symptoms are due, not to ulcer, but to intestinal stasis. Be this as it may, a diagnosis of gastric ulcer cannot be made on the clinical history alone, and we are not justified from such a history in assuming that the carcinoma has originated in an ulcer. So far from the clinical evidence being in favour of this view, it is absolutely opposed to it. The case may be

stated as follows: If it be true that 60 per cent. of chronic ulcers are, or become, malignant, then it follows that often we must perform gastro-jejunostomy for ulcers which we believe to be innocent but which are in reality malignant. Therefore a large number of these patients should die subsequently from gastric cancer. We know that is not the case. Those who have investigated this point tell us that the proportion of those who die from carcinoma after gastro-jejunostomy for supposed simple ulcer is about 2 per cent. In my own cases 2.5 per cent. of the patients are said to have died subsequently from cancer. Further investigation into these cases has made me sceptical as to accepting such estimates. In the main they are based on statements made by the patients' relatives. Although death was attributed to cancer in 2.5 per cent. of those on whom I have performed gastro-jejunostomy for ulcer, I have been able to discover only one case in which the cancer was indubitably gastric, and in that case it was not at the site of the original ulcer. In the majority of the cases there was no certain proof as to the existence of cancer, and in others there was a primary cancer elsewhere than in the stomach. Further, if it be true, as has been alleged, that in 60 per cent. of the cases of gastric ulcer there is evidence of malignancy, then the logical conclusion is inevitable that in course of time every gastric ulcer will become malignant, which, as Euclid would say, "is absurd."

For many years I have been asking this plain and straightforward question: If it be true that gastric ulcer is so frequently the precursor of gastric cancer, why is it that a large number of patients do not die after gastro-jejunostomy performed for supposed simple ulcer? So far not even the late Admiral Sir Percy Scott's intelligent midshipman has come to the rescue, for as yet I have received no answer. This is not surprising, as the only two possible answers impale the opposition on the horns of a dilemma. Patients seldom die from gastric cancer after gastro-jejunostomy for supposed simple ulcer because either the ulcers are rarely malignant or because gastro-jejunostomy cures cancer. Those who teach that gastric cancer usually originates in gastric ulcer can take what comfort they can gain from either answer.

The pathological evidence has been based on the finding of small downgrowths of epithelium near the edge of the ulcer, which downgrowths are regarded as evidence of malignancy. In a recent admirable paper<sup>2</sup> Dr. J. H. Dible has given cogent reasons for disregarding these assumptions. I submit that the clinical reasons I have stated above are a death-blow to this pernicious boggy. Dr. Dible has completed the obsequies by cremating the corpse. *Requiescat in pace!*

Thirdly, it has been alleged that partial gastrectomy is less likely to be followed by jejunal or gastro-jejunal ulcer. This may or may not be true. I am old enough to remember that in the early days of gastro-jejunostomy a reason urged in favour of the posterior operation was that it was never followed by a jejunal ulcer. Indeed, it was a good many years after its introduction before a jejunal ulcer was reported as following this operation. Now we know that secondary ulceration is at least not less frequent after the posterior operation than after the anterior method.

**THE REMOTE RESULTS OF GASTRO-JEJUNOSTOMY.**  
 What are the remote results of gastro-jejunostomy? As a contribution to this discussion I have reviewed my cases of gastric and duodenal ulcer for the ten years ending 1923, and the results are tabulated in Table I.

TABLE I.—Statistics of Gastro-jejunostomy, 1913-1923

|                  |     |     |    |
|------------------|-----|-----|----|
| Recovered        | ... | 110 | 82 |
| Died             | ... | 37  |    |
| Died since*      | 33  | 57  |    |
| Fairly well      | 61  | 43  |    |
| Quite well       | 316 | 172 |    |
| Bad result       | ... | 523 |    |
| Untraced         | ... | 4   |    |
| Gastric ulcer    | ... |     |    |
| Duodenal ulcer   | ... |     |    |
| Gastric+duodenal | ... |     |    |

\*Cured of gastric trouble.  
 Adding together those who are quite well, those who are fairly well—that is, are well so long as they take some care

in their diet—and those who have died from other diseases, but were quite well after their operation, it is seen that 82 per cent. may be regarded as cured.

The percentage of cures is lower than in my previous series, and lower than the percentage given by some other writers. There are two reasons for this. First, I have taken the percentage as that of all cases submitted to operation, and not the percentage only of those patients who recovered and have been traced. All the untraced cases are counted as "not cured." If, as is done by some writers, the untraced cases were disregarded, and the percentage of cures calculated with regard to the cases traced, the cures would be 91 per cent. Obviously, however, this is a doubtful method of representing the case. Secondly, the series includes nearly 300 operations on war pensioners at the Ministry of Pensions hospital, and it is these cases which reduce the percentage of cures. Most of the pensioners were bad subjects, out of work and in straitened circumstances, and not in a position to pay careful attention to their diet. For the same reason the incidence of jejunal ulcer among those patients is high. I am well aware of the danger of making any assumptions in drawing conclusions from statistics. As Sir Berkeley Moynihan once said wittily, "statistics may be made to prove anything, even the truth." Nevertheless I think it is justifiable to point out that if even half the untraced cases were well, the percentage of cures would rise to 88 per cent. It will be noted that only 7 per cent. of the cases were ascertained to be unsatisfactory. I think it is not an exaggeration to say that in patients who can and do take reasonable care of themselves the proportion of cures is over 90 per cent. The Mayos, Moynihan, Sherren, and others have reported a like proportion of successes.

Up to the year 1907 the anterior operation was the method I employed. In the year 1906, in the columns of the *Lancet*, I had a long and friendly clash of arms with Sir Berkeley Moynihan, who thrust and parried with that polished dialectic rapier which he handles with such skill. He disagreed with my advocacy of the anterior operation, and prophesied that soon I would be a convert to the posterior method. Twenty years later, in spite of those rapier thrusts, I am still alive—an unrepentant heretic. As a result of Sir Berkeley's persuasion and a visit to the Mayo Clinic I adopted the posterior method. During the ensuing years the impression grew upon me that the remote results of the posterior method were less good than I had obtained in former years by the anterior operation. In the course of time this impression became a conviction, a conviction possibly not demonstrable by statistics, but one the truth of which has been forced on me by a comparison of the late results in my patients. My experience is that the good results of the anterior operation are better than the good results of the posterior operation. Consequently, since the war I have adopted the anterior method almost exclusively, and in Table II are set out my cases divided into two groups.

TABLE II.—Results of Gastro-jejunostomy.

|  | Anterior. | Posterior. |
|--|-----------|------------|
| Recovered ... ..                             | 384       | 111        |
| Died ... ..                                  | 4         | 0          |
| Quite well ... ..                            | 244       | 72         |
| Fairly well ... ..                           | 52        | 9          |
| Died since (cured of gastric trouble) ... .. | 27        | 6          |
| Bad result ... ..                            | 28        | 9          |
| Untraced ... ..                              | 33        | 15         |

As the proportion of untraced cases in the posterior method group is higher than in the anterior group, it is not possible to make a fair comparison of the results of the two methods. What difference there is in favour of the anterior method, but I do not suggest drawing any comparisons from these statistics.

#### HOW DOES GASTRO-JEJUNOSTOMY ACT?

For many years I have taught that gastro-jejunostomy is a physiological operation. The anastomosis between the stomach and jejunum allows small quantities of bile and pancreatic juice to "back-flow" into the stomach and so reduces the acidity of the gastric contents, and also neutralizes hypersecretion. This is Nature's method of lowering the acidity of the gastric juice. In health the

gastric contents are modified by the intermittent regurgitation of bile and pancreatic juice through the pylorus. Gastro-jejunostomy increases this reflux and allows of it even when there is pyloric spasm. For years I was as one crying in the wilderness. This hypothesis was received with scepticism by many and scoffed at by some. To-day, many of the "multitude make virtue of the faith they have denied." The admirable experimental work of Dr. Charles Bolton has proved the correctness of this hypothesis. As yet no other satisfactory explanation of the beneficent effects of gastro-jejunostomy has been put forward. Anterior gastro-jejunostomy results in a slightly greater "back-flow" of alkaline secretion than does the posterior operation, and this may be the reason why the results of the anterior operation are slightly better than those of the posterior operation. Operations of the Y type are quite unsuitable for the treatment of gastric and duodenal ulcers, as they short-circuit the bile and pancreatic juice so that they do not reach the stomach.

#### JEJUNAL AND GASTRO-JEJUNAL ULCERS.

The most serious remote complication of gastro-jejunostomy is the occurrence of a jejunal or gastro-jejunal ulcer. There were twelve instances of this in the present series (2.4 per cent.). This is slightly above the probable incidence of the complication, but six of the cases occurred among the pensioner patients, owing to the causes I have already mentioned. In eight instances the secondary ulcer followed the anterior operation (2 per cent.), and in four instances the posterior operation (3.6 per cent.). It would, however, hardly be fair to infer from such a number of cases that there is this difference in the incidence of this complication after the anterior and posterior operations. In three instances the result was fatal—in one case from a perforation, fatal before any operation could be performed, and in two others, in both of which the ulcer perforated into the colon, death followed the second operation. Whether or not secondary ulceration be more frequent after the posterior method, there can be no question that after this operation it is far more difficult to treat. Operation for a gastro-jejunal ulcer following the posterior operation is one of the most difficult, if not the most difficult, task in surgery. After the anterior operation the surgical treatment of a gastro-jejunal or jejunal ulcer, although not easy, is a very different problem. The predisposing if not the exciting cause of secondary ulceration is hyperacidity. At any rate I have not seen a case in which marked hyperacidity was absent. It is, therefore, a complication which may be prevented by dietetic and medical treatment. It is met with rarely in private patients, and when it occurs it is usually in those who after the operation have lived "not wisely but too well."

#### THE PRESENT POSITION OF GASTRO-JEJUNOSTOMY.

What, then, is the present position of gastro-jejunostomy in the treatment of gastric and duodenal ulcers? Gastro-jejunostomy is the operation of choice for all cases of gastric ulcer except those in which there is a suspicion that the ulcer is a cancerous one. In his Hunterian Lecture in 1920 Sherren expressed the opinion that "gastro-jejunostomy for gastric ulcer will become the less frequent operation." Further experience has modified his views, for this year he has said: "My mature opinion is that gastro-jejunostomy is still the most satisfactory treatment for duodenal ulcer and all cases of free gastric ulcer, and that its results equal, if they do not excel, those of any other major surgical operation." I go further than this, for I believe that gastro-jejunostomy will in most instances bring about the healing of an ulcer even when it has eroded the pancreas. This is no mere surmise, for in a number of instances I have seen a large excavating ulcer completely healed in patients who have died from some other cause years after the performance of gastro-jejunostomy. The results of gastro-jejunostomy are so satisfactory that more drastic measures may be wisely and safely deferred until the simpler operation has been tried and failed.

While there may be difference of opinion as regards the value of gastro-jejunostomy in the treatment of gastric ulcer, there can be no question that success can be attained by gastro-jejunostomy in over 90 per cent. of the cases of

duodenal ulcer. Therefore, in my view, duodenectomy is a totally unnecessary operation; it is one of the most tedious operations in surgery, the difficulties and dangers being far greater than with gastro-jejunostomy, and the remote results problematical.

In my opinion there is a further indication for gastro-jejunostomy—namely, that it should be part of the treatment of a perforated gastric or duodenal ulcer. I am convinced that it is a life-saving measure. When performed in addition to suture of the perforation and drainage, convalescence is smoother and more uneventful and the patient's recovery is more speedy and more sure.

It may not be amiss to repeat that gastro-jejunostomy should never be performed except when there exists an ulcer which can be seen and felt. It should never be done on a clinical diagnosis, however clear and definite the symptoms. Further, gastro-jejunostomy will not cure tabes dorsalis, migraine, gall stones, or cancer of the intestine; yet more than once I have operated on patients on whom gastro-jejunostomy had been performed for one or other of those conditions. Neither will gastro-jejunostomy give good results if a gall stone or a diseased appendix be left in the abdomen. Often we can learn more from our failures than from our successes. It is pertinent to inquire whether the unsuccessful cases would have been in the list of cures had some more radical procedure than gastro-jejunostomy been the operation of choice. In the series I have given there are 7 to 8 per cent. of known failures; of these approximately 2 per cent. are due to jejunal or gastro-jejunal ulcer, and 2 per cent. to chronic disease such as phthisis, chronic nephritis, or cancer elsewhere than in the stomach; 3 per cent. were apparently due to failure to reduce the gastric acidity, and 0.5 per cent. to adhesions or other complications incidental to abdominal operations. It is open to grave doubt whether partial gastrectomy *per se* would reduce the number of these unsuccessful results; on the other hand, there is no doubt that they would be reduced if the patients could and would keep to a more suitable diet.

#### THE IMPORTANCE OF AFTER-CARE.

This cannot be emphasized too strongly, for gastro-jejunostomy is but an incident in the treatment of gastric and duodenal ulcers. A prolonged period of restricted diet is imperative, especially in cases in which there is hyperacidity before operation. In all cases of hyperacidity increase in diet should be gradual and should be controlled by gastric analysis at regular intervals.

In dealing with some of the poorer hospital patients it is pathetic to restore a patient to health only to see the result of a successful operation marred through the inability of the patient to obtain adequate and suitable food. Two urgent needs to-day are convalescent hospitals where patients could have a prolonged period of rest and careful dietary amid healthy surroundings, and a system of "after-care" by which treatment could be continued on their return to their homes. Until these desiderata be secured our work is but half done. Through lack of them the value of the great work done by our hospitals is depreciated enormously and a corresponding economic loss falls on the nation. No detail is too trivial if it can aid us in our quest for perfection. We must use all and every means in our power to attain this ideal. With more efficient after-treatment gastro-jejunostomy will yield even better results than we know now.

In conclusion I cannot do better than quote a sentence from a paper by Moynihan,<sup>3</sup> which admirably expresses my own view: "I am an ardent and a sanguine advocate of this operation [gastro-jejunostomy], than which I think there is none in all surgery more completely satisfactory." These words are as true to-day as when they were written. With them I am in cordial agreement. I share the ardour and conviction of his advocacy. The worth of gastro-jejunostomy has been proved by time, and its value is inestimable provided it is used with judgement and with discretion in its proper place and with that

"Good sense, which only is the gift of Heaven,  
And tho' no science fairly worth the seven."

#### II.—PROFESSOR H. FINSTERER, M.D., Vienna.

In my opinion the results of routine gastro-enterostomy in gastric and duodenal ulceration are not satisfactory because (1) the operation does not generally lead to the healing of the ulcer; (2) gastro-duodenal ulcers are not a very unusual complication of the operation; (3) haemorrhage from an unhealed ulcer is fairly frequent, and a perforation after gastro-enterostomy is not unknown. These were some of the reasons why certain Continental surgeons, such as Riedel, Payr, Clairmont, Haberer, and I myself decided in favour of the resection instead of gastro-enterostomy in gastric and duodenal ulceration. Since 1919 I have employed resection of the stomach in almost all cases which were not complicated with acute perforation; I have performed 593 resections for gastric and duodenal ulcers and 5 gastro-enterostomies for duodenal ulcer. It is evident from these figures that in my opinion gastro-enterostomy occupies a very minor position in gastric and duodenal surgery.

The objections to resections are that the mortality is much higher than in gastro-enterostomy, and that despite the resection recurrences are observed. In my material the mortality in resection for gastric ulcers was high (16.6 per cent.) before the war and during the war because of my lack of experience in resections of the stomach up to then, and because at that time in resections of penetrating ulcers the base of the ulcer was always excised from the pancreas because of a suspicion that these ulcers might become malignant. These resections of part of the pancreas led in many cases to pancreatitis, and increased the mortality. Besides this, during the war deaths from peritonitis without leakage were frequently observed because of poor asepsis due to war conditions. Since 1919 in resections for gastric ulcers the mortality has become lowered to 4 per cent. (175 resections with 7 fatalities) and in duodenal ulcers to 2 per cent. (357 cases with 7 fatalities). Fatalities were due mostly to peritonitis; there was one case of embolism, and haemorrhage occurred after operation in a patient suffering from severe cirrhosis of the liver in addition to his ulceration. But there was no fatality through operative shock or pneumonia in all the gastric resections, although 87 patients were from 60 to 78 years of age.

It is remarkable that resection for duodenal ulcers shows better results than for gastric ulcers. The dangers of this operation were avoided, since in all cases of duodenal ulcer in which the penetrating ulcer had extended as far as the papilla, or where the common duct could not be separated from the callosities, the ulcer was left in, and the stomach resection for exclusion was performed. In 1918 I recommended this method in order to avoid the gastro-jejunal ulcer, which was frequently (15 to 27 per cent.) observed after Eiselsberg's exclusion. My method was later employed in many clinics (de Quervain, Zaaier, Reichel, Burk, etc.), whereas Haberer rejected this method, because he affirmed that the excluded pylorus would cause a recurrence. The removal of the pylorus raises the mortality through leakage in the blindly closed duodenal stump. In 72 resections for exclusion in which the pylorus was not removed I had 2 fatalities—a mortality of 2.7 per cent.; whereas in 29 cases in which the pylorus was removed there were 5 fatalities—a mortality of 17.4 per cent.; 3 of the deaths were due to peritonitis following on a leakage of the blindly closed duodenal stump. As in my material the permanent results have not been improved through the removal of the pylorus I as a rule perform the typical resection for exclusion and remove the pylorus only in those cases in which the ulcer is located in the descending part of the duodenum, so that a safe closure of the duodenum can be expected. In these cases I put in a rubber tube to prevent peritonitis due to leaking.

In very hypertrophic stomachs the excluded part of the antrum must be greater; in those cases it may be advantageous to remove the excluded part with the pylorus and the duodenum in a second operation four to six weeks later, which is very easy, as the duodenal ulcer will already be healed. In this way the dangerous resection of the penetrating duodenal ulcer is done in two stages, each being

almost without danger. In cases with a very movable descending part of the duodenum I performed an end-to-side anastomosis between the partially closed stomach stump and the mobilized descending part. The advantage of this method is that good permanent results can be obtained with less extensive resection of the stomach (only one-third to one-half), as recurrence in the duodenum below the papilla is not to be feared.

The method of resection is of some importance for the immediate and permanent results. The method I generally use is a modification of the Billroth II developed by Hofmeister and myself. With this modification the disadvantages of the Billroth II method and its modification after Krönlein-Mikulicz—namely, the retrograde filling of the duodenum and bursting open of the duodenal closure followed by peritonitis—can be avoided. Up to now I have not observed any leakage or suture insufficiency.

Down to 1914 I performed the sleeve resection of gastric ulcers in 9 cases, but the permanent results were not satisfactory. Since 1914 I have always removed the pylorus. In ulcers reaching from the pylorus to the cardia or located near the cardia I perform a curved resection. In penetrating ulcers the stomach is separated from the base of the ulcer (pancreas, liver), leaving the base in. Since it is impossible to recognize the malignant degeneration of a gastric ulcer during the operation, I have performed no gastro-enterostomy for the last seven years, but have resected all gastric ulcers.

The Billroth I method is greatly favoured by Haberer; I use this method only in cases in which the duodenum is very broad, as otherwise one has to deal with stenosis of the anastomosis. In old or cachectic patients the danger of leakage is very great, as the power of healing is not sufficient and the sutures cut through on the third to the fifth day because tension is caused by every contraction of the stomach. With Haberer's modification there is no danger of stenosis and less danger of leakage, therefore I prefer this method to the original Billroth I method.

In acute profuse haemorrhages resection is the best method of stopping the bleeding. The results depend first on the duration of the profuse haemorrhage and the degree of the degeneration of the parenchymatous organs through anaemia. In the early operation (up to twenty-four or even forty-eight hours after the onset of the profuse bleeding) the results of the resection are good (26 resections with one death in a case of very extended gastro-jejunal ulcer=3.8 per cent. mortality), while in late operations, on the third to the fourteenth day, the results are unsatisfactory (28 resections with 7 fatalities=25 per cent.).

The mortality in resections for ulcers ranges from 2 to 5 per cent.; it is not much higher than the mortality of gastro-enterostomy, especially if the deaths from perforation or haemorrhage of the ulcers which will not heal are included. Nordmann states that in these cases the mortality with resection is lower (4.5 per cent.) than the mortality with gastro-enterostomy (4.7 per cent.). In Eiselsberg's clinic the mortality in resection was 3 per cent. in 449 cases during the last few years. The best results were achieved by Moynihan, who reported a mortality of 1.6 per cent. in resection for gastric ulcers. In over 500 operations—gastro-enterostomy and gastro-duodenostomy—for duodenal ulcer Moynihan has had no deaths during the last ten years.

The permanent results are of the greatest importance, as that method which shows not only the lowest mortality but also the greatest percentage of good permanent results can alone be the method of choice. The value of a method can be demonstrated through useful statistics. To obtain absolutely reliable statistics it would be necessary to get answers from all patients or to re-examine them. Statistics in which more than 10 to 15 per cent. of untraced cases are included cannot prove the value of the operation, as, especially among these cases, there may be many uncured patients, who do not reply because they believe that an unsatisfactory operation was the cause of their not being cured. Of 450 patients on whom I performed resection between 1911 and 1923, 43 were untraced—9.5 per cent. In many statistics this percentage is higher—15 to 30 per cent. and more.

The permanent results of resections for gastric ulcers are very satisfactory. Among 105 resections which were performed from 1911 to 1923, 103 have been cured=98 per cent. The patients have no diet limitations; they have gained up to 60 lb. in weight, and are able to do hard work. Two patients are restricted to a certain diet; otherwise they complain of some stomach symptoms—heartburn and eructation; in these cases an entero-anastomosis was also performed. I wish to emphasize the fact that after the resection it is necessary to keep to a certain diet for two or three months only, then the patient can eat any food, whereas after gastro-enterostomy careful dieting is always necessary (Moynihan).

Of 236 resections for duodenal ulcer which were performed from 1916 to 1923, 223 (94 per cent.) have been cured, 8 improved, and 5 not cured (2.1 per cent.). Among these 5 cases there are 2 recurrences of duodenal ulcer after operation by the Billroth I method, and one case of gastro-jejunal ulcer. This is the only case of gastro-jejunal ulcer among 292 resections. After a more extended stomach resection this patient has now been cured.

The permanent results with stomach resection for exclusion are not so good, as there have been 9 per cent. failures. As in cases of removal of the pylorus the permanent results are worse (53 per cent. of cures) than in the typical cases in which the excluded pylorus was left in (88 per cent. of cures), it is impossible that the excluded pylorus should be the cause of failure, as Haberer asserted. According to my experience the good permanent results depend on the size of the part of the stomach removed. In 1919 I resected only one-third of the dilated stomach, and in this way the failures can be explained. Through a more extensive stomach resection the patients could be cured.

It is very important to realize that almost as good permanent results can be achieved with the stomach resection for exclusion as with resection of the ulcer, if a sufficiently large part of the stomach is removed. The resection for exclusion is much easier and less dangerous than the resection of a penetrating duodenal ulcer, and it would be a great advantage if this method were performed instead of gastro-enterostomy. It cannot be expected that the results with gastro-enterostomy (which method is recommended by Haberer for such cases) will be better than those when gastro-enterostomy was used in every case. And at that time Haberer had only 37 per cent. good permanent results, while other surgeons (Müller, Payr) had from 50 to 70 per cent. I do not reject gastro-enterostomy altogether, but I reserve it for old patients without hyperacidity who are not in danger of getting gastro-jejunal ulcer.

My view that the extent of the resection and not the removal of the pylorus decides the permanent results seems to me to be proved by the following two cases.

Two brothers were operated on in 1919 for gastro-jejunal ulcers after gastro-enterostomies. I removed half of the dilated stomach with the pylorus and the old duodenal ulcer, and performed a Y-shaped anastomosis without giving relief; heartburn, haemorrhage, and severe pain continued, so that half a grain of morphine daily was required. In 1921 I operated again on both, and found big gastro-jejunal ulcers penetrating into the pancreas; after an extended resection of the stomach, leaving behind only one-fifth, a Y-shaped anastomosis was performed. Recovery followed and since that time the patients have remained well; they can eat anything, and have gained more than 30 lb. in weight during five years' observation.

The fact that in a dilated stomach scarcely more than the antrum is enlarged is very important, but not commonly known, and so it is not taken into consideration. Therefore after removal of two-thirds of a greatly dilated stomach there remains more than one-third of a normally sized stomach; this is the explanation of the recurrences. In a really extensive stomach resection the whole lesser curvature is removed.

In the radical operations for gastro-jejunal ulcer the immediate results are satisfactory—68 resections with 4 deaths—a mortality of 7.3 per cent. In order to get good permanent results it is necessary to make an extensive resection of the stomach and to avoid the Y-shaped

anastomosis which favours the recurrence. I have not performed Y-shaped anastomosis for four years. By this method also, and even after repeated operations, permanent recovery may be expected. In two of my cases four operations were performed by other surgeons without success. One of these was a resection of the stomach (antrum and pylorus); through a very extensive resection these patients were cured.

Of especial interest is the success in the following case of a man aged 33. He was first treated by a posterior gastro-enterostomy for duodenal ulcer followed by excision of the anastomosis for gastro-jejunal ulcer, and anterior gastro-enterostomy with entero-anastomosis. The antrum with the pylorus and anastomosis loop were next excised for a large gastro-jejunal ulcer according to the Billroth II method. Owing to stenosis resulting from gastro-jejunal ulcer a further gastro-enterostomy was performed. A gastro-jejunal ulcer formed on this anastomosis with perforation into the transverse colon (fistula gastro-colica) and was followed by resection of the transverse colon, jejunum, and a great part of the stomach, only one-fifth being left; lateral anastomosis of the colon, end-to-end anastomosis of the jejunum, and below this an anastomosis between stomach and jejunum (Hofmeister-Finsterer method). Each of these operations was performed by a different surgeon, the last by myself. Since that time, two years ago, the patient has remained absolutely well and has gained more than 40 lb. in weight.

The symptoms of too small a stomach do not depend on the size of the remaining part of the stomach, but on the width of the anastomosis. In my cases they have more frequently been observed in resections after the Billroth I method, where a greater part of the stomach remained than in my operation, but the anastomosis became narrowed.

The possibility of severe diarrhoea is also an objection to extensive stomach resections, but up till now I have not met this complication. I should like to emphasize the fact that I have not yet observed cancer develop in a stomach stump after the large resections.

#### CONCLUSION.

As in my material the immediate mortality in resections for ulcer is not much higher than in gastro-enterostomy, and the permanent results are much better, I prefer resection to gastro-enterostomy.

In gastric ulcers I perform resection in every case, even in old patients, because the danger of malignant degeneration is great, and it is almost impossible to recognize the degeneration during the operation.

In duodenal ulcers I prefer resection of the ulcer with a large part of the stomach. In non-resectable ulcers I perform the stomach resection for exclusion. As the permanent results depend on the extension of the resection, I remove the pylorus only if an absolutely safe closure of the duodenum can be expected. In old patients with a non-resectable duodenal ulcer I perform a gastro-enterostomy.

In every resection the pylorus and two-thirds of the normally sized stomach are removed, and, as a rule, an end-to-side anastomosis is performed between the reduced opening of the stomach stump and the first jejunal loop. As the Billroth I method shows a higher mortality and no better permanent results, I do not consider it the method of choice.

In gastro-jejunal ulcers it is necessary to perform a very extensive stomach resection and to avoid the Y-shaped anastomosis. In this way a good permanent result can be obtained after repeated operations, therefore I never refuse an operation even in apparently incurable cases.

#### GENERAL DISCUSSION.

Mr. K. W. MONSARRAT (Liverpool) said that questions of this character might be discussed from two points of view: they could either analyse results of different technical procedures, or they could discuss the subject from the other standpoint having regard to the nature of the morbid process requiring remedy. He preferred to discuss the subject of gastro-enterostomy from the second point of view. In stenotic lesions the problem was simple as there was no longer active ulceration. The patient had

recovered from his morbid process, but was left with a mechanical obstruction. Uniformly good results were obtained by a short-circuit. The problem was more complicated when actual ulceration was present. Full consideration of recent work supported the view that ulcers in the upper alimentary canal were secondary to disordered mechanism. Preceding the development of duodenal ulcers there occurred a hypertonus leading to rapid and early discharge of gastric contents into the duodenum, and a late pyloric spasm which checked regurgitation and produced a retention of gastric secretions during the hunger period. The result of this disorder was that as soon as food entered the stomach the duodenum was flooded with active gastric juice, which was damaging to its mucous membrane and produced necrosis in many cases. The problem was how to arrest the process of ulceration; how to suppress the hypertonus. Gastro-enterostomy could diminish the hypertonus if it provided a sufficient discharge of jejunal contents into the stomach. The effect of the discharge of fluid or food into the stomach, whether by the oesophagus or any abnormal channel such as a gastro-jejunal stoma, was to bring about relaxation of the hypertonus. With active ulcers, however, this was not enough. The ulcer should be protected from contact with gastric secretions, and this could be brought about by a temporary pyloric occlusion. The speaker added that hypertonus might persist in spite of gastro-jejunosomy, when it did, it depended upon such causes as mouth infections, infections of other viscera, irritability caused by certain foods, and certain forms of intoxication, such as that of tobacco. These primary causes of the hypertonic habit had to be sought for and eliminated, otherwise a definite risk of an ulcer developing in the region of the anastomosis was run.

In simple gastric ulceration the disordered function was characteristically different; it was pyloric spasm of early onset, and hypotonus. The result was retention of gastric contents in the stomach for an unduly long period. On the whole there was a tendency to hyperacidity, but he no longer considered free acid content of the gastric juice of primary importance in regard to ulcer production either in the stomach or duodenum. The remedy for gastric ulceration was excision of the actual ulcer area and the prevention of gastric stasis. Gastro-enterostomy did this, but the site of the anastomosis was of prime importance: it should be as near the pyloric end as practicable and of ample size. If high gastro-jejunosomy was performed there would remain a large pyloric segment where stasis persisted, and if this obtained, a recurrence of ulceration in this segment was likely. In actual experience they all knew that this was what occurred. In gastric ulcer gastro-jejunosomy was essentially a drainage operation, a short-circuit with an object in view which was primarily mechanical. When the extent of the lesser sac towards the right made it difficult to obtain an anastomosis with the pyloric part of the stomach he discarded gastro-jejunosomy for pyloroplasty. In the treatment of duodenal ulcer they aimed at relieving the hypertonus by making a large opening, through which regurgitation or admixture of jejunal and gastric contents would be considerable. The position of the anastomosis was not of prime moment. In gastric ulcer they desired to bring about an early and complete emptying, and the position of the anastomosis in relation to the pylorus was of great importance. In both cases the speaker was in the habit of making the gastric incision parallel to the greater curvature. Unless the stomach was much dilated he found it impossible to obtain as large an opening as wanted by making a vertical gastric incision.

Lastly, Mr. Monsarrat referred to a certain type of case he met from time to time, where he failed to find actual ulceration in the duodenum, although the clinical history was typical and the radiological evidence showed typical derangement of gastric function. In some of these cases, although there was no ulcer, there was evidence of active duodenitis. He did not hesitate to perform a gastro-enterostomy with temporary occlusion of the pylorus, just as though there were duodenal ulceration present. He believed that duodenitis was due to the same disorder of mechanism as duodenal ulcer, and was the first stage in the development of actual ulceration.

Mr. CHARLES ROBERTS (Manchester) said that his contribution to the discussion was based on the close observation and a follow-up of 157 operations of gastro-jejunostomy for ulcer, which he performed at the Manchester Royal Infirmary during the five years ending December, 1925. He believed that a true estimate of the role of gastro-jejunostomy in the treatment of ulcer could be most accurately formed by regular and prolonged observation of patients after operation. Posterior gastro-jejunostomy alone had been performed for duodenal and pyloric ulcers in the great majority of cases. For small gastric ulcers the operation had been combined with local excision of the ulcer when practicable. The appendix had been removed as a routine, focal sepsis dealt with, and the teeth carefully attended to. Printed general instructions, with special directions as to diet, had been given to all patients, and a powder containing magnesia ponderosa and the carbonates of bismuth and calcium had been prescribed for at least six months. Five patients had been readmitted for symptoms necessitating a further operation. In one of these, where the operation had been done for an irremovable ulcer, signs of malignancy were present. One case of duodenal ulcer was readmitted for recurring haemorrhage. In one case subacute intestinal obstruction followed anterior gastro-jejunostomy. In another the appendix had been left owing to difficulties with the anaesthesia, and appendicectomy was followed by a successful result. One patient (the only one he had been able to find) developed a gastro-jejunal ulcer. This man, who lived in a fried-fish shop, had disregarded all instructions as to after-treatment. Two patients refused readmission, and one patient with pyloric stenosis was operated upon again elsewhere. Nine, all of whom were cases of duodenal ulcer, had suffered from minor digestive disturbances, chiefly in the form of an inability to digest certain articles of diet. Instructions given for after-care had not been rigidly observed.

His observations led him to the following conclusions: Partial gastrectomy should be performed whenever practicable, for, apart from other reasons, malignancy might follow even if it was not already present. Local excision combined with gastro-jejunostomy was the most successful of all operations for ulcer. Anterior gastro-jejunostomy should be avoided whenever possible owing to its mechanical disadvantages. In the case of haemorrhage or the bleeding type of duodenal ulcer, a direct attack should be made on the ulcer itself. The appendix should be removed as a routine. Gastro-jejunal ulcer, recurrence of ulcer, formation of a fresh ulcer, and minor digestive disturbances could be almost entirely prevented if careful supervision and after-treatment were carried out. The speaker wished to emphasize that point because so little stress as a rule was laid upon the importance of after-treatment in surgical textbooks and communications.

Gastro-jejunostomy was to be looked upon as an adjunct to medical treatment and not entirely curative. The operation itself was to be regarded, not as the final treatment, but the commencement of a more efficient treatment. Under these conditions the results were so satisfactory that any alternative procedure, more mutilating in character or involving a higher mortality risk, was unnecessary and unjustifiable, and should only be resorted to as a second-stage operation.

Mr. E. DEANESLY (Wolverhampton) said that the question debated was whether gastro-jejunostomy retained its position as the best means of treating gastric and duodenal ulcers. Mr. Paterson maintained emphatically that it did, while Professor Finsterer said that he rarely employed it and recommended various more radical operations. Mr. Deanesly agreed in the main with Mr. Paterson. It could not be denied that gastro-jejunostomy gave excellent results in a very large percentage of cases, and it was difficult to understand the extraordinary discrepancy in the percentage of favourable results recorded by different surgeons of acknowledged eminence and experience. It could not, however, be denied that every surgeon had a certain percentage of cases of duodenal ulcer which gastro-jejunostomy failed to cure, and very few surgeons now, with the exception of Mr. Sherren, regarded this operation by itself as a satisfactory treatment for gastric ulcers. With

regard to the larger and more deeply penetrating ulcers of the duodenum, especially those in which serious haemorrhage had occurred, and also those ulcers in which an active ulceration was accompanied with marked stenosis, gastro-jejunostomy did not give good permanent results. For the last few years he had been treating such cases more and more frequently by Finney's gastro-duodenostomy, which was really a pyloroplasty, and he had had most encouraging results. This operation had the advantage of removing both pyloric stenosis and pyloric spasm. In smaller duodenal ulcers he had even contented himself with a simple Rammstedt's operation on the pyloric sphincter. Most textbooks spoke rather disparagingly of Finney's operation or exaggerated its difficulties, which were really no greater than a gastro-jejunostomy in most cases, and he had heard that Finney himself rarely practised the operation now. However that might be, it seemed to him that it had such obvious advantages in placing the ulcer at rest and in preventing the holding up of food in the stomach, with resulting increase in acidity, that he thought more surgeons should give an extended trial to this method before resorting to such a drastic and difficult procedure as resection of the duodenum.

Mr. A. B. MITCHELL (Belfast) agreed with Mr. Paterson that gastro-jejunostomy held the field in the treatment of duodenal ulcer. The ulcer, however, should at the same time be infolded or excised. If a severe haemorrhage had occurred the ulcer would almost always be found on the posterior surface or pancreatic border of the duodenum. In such cases he made it a rule to ligature the duodenal branch of the pancreato-duodenal artery. At the Annual Meeting in Belfast in 1909 he had advocated the performance of gastro-jejunostomy in the treatment of duodenal perforation, but met with no support. It had been the routine practice in his clinic since that time, except where shock was profound and very rapid work was essential. He was very pleased to hear Mr. Paterson advocate it so strongly. Initial shock on perforation depended on the character and amount of extravasation. In duodenal perforation the extravasated material was aseptic and small in amount, because the moment the perforation occurred the pyloric sphincter suddenly contracted and remained contracted till it was wearied out or some indiscreet person put it to sleep by morphine. In either case a further leakage occurred. In gastric perforation the case was different and leakage was continuous. If the stomach was dilated and the perforation large, the peritoneum was rapidly drenched with material which might be highly toxic and cause the most profound shock. Such patients could bear very little handling. "Get in quickly and get out quicker" must be their rule. Apart from this, in gastric perforation he thought the question of gastro-jejunostomy should always be considered after the perforation had been closed. As regards the treatment of chronic gastric ulcer, gastro-jejunostomy, with or without partial gastrectomy, was now the recognized procedure. It was generally accepted that excision of the ulcer or infolding the ulcer would rarely in itself result in cure. It was also agreed that gastro-jejunostomy alone was not sufficient—the ulcer itself must be dealt with. Mr. Mitchell confessed to a great hesitation in resecting a large portion of healthy stomach for the cure of a small simple ulcer, say the size of a sixpence, high up on the lesser curve in a young patient. These ulcers might be treated by infolding—the through-and-through stitch around the ulcer being drawn so tight that the blood supply was cut off. It would then undergo necrosis and digestion. Leakage was prevented by a Lembert suture. A gastro-jejunostomy was then performed at the upper level of the pyloric segment. He could not follow Mr. Sherren in anastomosing the jejunum above the ulcer at the fundus of the stomach. Where the ulcer was in the lower segment or where it was adherent to the pancreas or liver it must be freely separated. The question of partial gastrectomy by the method of Polya would then arise. It was the operation of choice unless the damage to the stomach was very slight. He agreed that the mortality was very low and convalescence rapid. It was, however, too soon to say whether this operation was free from such sequelae as peptic ulcer.

# MEMORANDA.

SEPT. 25, 1925]

Where gastro-jejunostomy was performed *per se* the ideal opening, after due allowance had been made for normal contraction, should approximately equal the transverse diameter of the jejunum. It was a simple mechanical fact that the jejunum could not carry away more contents than its normal lumen when comfortably distended would admit. For the purpose of emptying the stomach the very large opening so frequently made was obviously unnecessary. The normal outlet of the size of when the pylorus was fully dilated was exactly the size of the duodenum. It would seem reasonable to copy this principle. The farther they got away from Nature's standard the more likely they were to fall into error.

Sir WILLIAM DE COURCY WHEELER (Dublin) said that most surgeons would be guided in the management of gastric and duodenal lesions by judgement based on their own capabilities and the results of personal experience. He agreed with Mr. Herbert Paterson that no complicated surgery was justified in the case of duodenal ulcer. Perforation and haemorrhage had alone to be considered, and every ulcer, when possible, should be inverted or covered with a piece of omentum; when bleeding was part of the history, excision, cauterization, or the picking up and ligature of the vessels round the ulcerated area should be practised in addition to gastro-enterostomy. The speaker feared cancer following gastric ulcer, but in his experience the pendulum of surgical opinion had swung too much over in this direction; Mr. Herbert Paterson had, he thought, gone to the other extreme. He had had several cases come back years after gastro-enterostomy for ulcer with inoperable cancer. In his hands resection had given better results than excision, but resection was only necessary in a limited number of cases. Gastro-enterostomy was futile as a palliative operation and two-stage operations were seldom necessary. It was most important to empty the stomach before operation when resection was contemplated. Fatalities had occurred by regurgitation of fluid into the mouth during the application of the clamps when this elementary detail had been omitted. Judgement was the keynote to success, and he refused to be bound by those who insisted, on the one hand, that gastro-enterostomy was sufficient in all cases, or, on the other hand, by those who argued partial gastrectomy as a routine. The sleeve resection which he had advocated on a former occasion did not give as good ultimate results as might have been expected.

Dr. H. BRUCE (Toronto) said that gastro-jejunostomy was the most satisfactory operation. He feared the mortality that would take place if gastrectomy were performed by every surgeon.

Professor D. P. D. WILKIE (Edinburgh) pointed out that time was the surest test of the value of any method or procedure. The fact that after more than forty years the operation of gastro-enterostomy remained the recognized procedure for duodenal ulcer was the strongest proof of its worth as an operation. The problem resolved itself into two questions: first, did the operation give lasting relief or cure for either duodenal or gastric ulcer or for both in a large percentage of cases? and secondly, did it entail unfortunate sequels in any appreciable number of cases? He believed that this operation would remain the method of choice in all post-pyloric ulcers. It was seen at its best in cases of duodenal ulcer with some stenosis, and here they might anticipate 90 per cent. of satisfactory results. Where the duodenal ulcer was associated with a small hypertonic stomach and no stenosis the benefits of the operation were much less certain, and in this class of case medicine found its legitimate field. Where haemorrhage from a large posterior duodenal ulcer was the indication the results were still less certain, and permanent relief was not conferred in more than 60 per cent. of cases. Where there was an active florid gastric ulcer of the lesser curve gastro-enterostomy, although by no means useless, was insufficient for cure in too large a percentage of cases to be considered the operation of choice. The success of partial gastrectomy had given it a vogue which he felt sure would not outlast the test of time. Local excision of the ulcer, and the treatment by cautery combined with gastro-enterostomy, although less dramatic in their performance

and in their immediate results, were, in his opinion, more logical operations. He did not wonder that a certain aftermath of poor results from gastro-jejunostomy occurred, considering the number of times this operation had been performed by all kinds of surgeons. Either the case was unquestionably due to bad surgery. Most of the bad results were unsuitable, the operation was indifferently performed, a coincident gastric ulcer was overlooked, the after-treatment was neglected, or infective foci were left untreated. Jejunum ulcer and bilious vomiting occurred occasionally in the practice of all surgeons. He believed that persistent hyperacidity was the deciding factor in the etiology of jejunal ulcer, and careful antacid treatment for some months after the operation was the surest safeguard against it. In all cases in which hyperacidity had been a feature prior to operation alkalis and belladonna should be given for some weeks thereafter. Where care in after-treatment was exercised, this complication would not appear in more than 2 per cent. of cases.

Post-operative vomiting of bile was almost always due to the opening in the mesocolon being too small. Where access through the mesocolon was restricted it was preferable to perform the anterior operation with a lateral anastomosis of the limbs of the loop, a procedure which, with some, had an undeservedly bad reputation. If the patient suffered from gastric flatulence with occasional bilious vomiting prior to operation, and no stenosis but rather a dilated duodenum was found, a duodenostomy in addition to gastro-jejunostomy would ensure post-operative freedom from vomiting. Persistent bilious vomiting did not occur in more than 3 per cent. of cases, and in most of these could be cured by a second anastomotic operation. The operation of gastro-duodenostomy was on physiological grounds preferable to gastro-jejunostomy in cases of duodenal ulcer. In male subjects, however, it was usually difficult to perform, and, in his experience, whilst the ultimate results were excellent, the convalescence was less smooth and the immediate effects less striking.

Mr. HERBERT J. PATERSON, in reply, said that on the whole the results of gastro-jejunostomy were eminently satisfactory; the mortality rate need not be greater than 1 per cent. He asked whether, on the supposition that 5 per cent. of the failures after gastro-jejunostomy could be cured by partial gastrectomy (an assumption which he declined to admit), it was justifiable, having regard to the small number of failures, to submit the remaining 95 per cent. of their patients to such a severe operation as partial gastrectomy, with its necessarily greater mortality rate. Surely the wiser course was to perform gastro-jejunostomy in the first instance, and to reserve more severe procedures for cases in which the simpler operation had been tried and had failed?

## Memoranda : MEDICAL, SURGICAL, OBSTETRICAL.

STOVAINE IN OTO-RHINO-LARYNGOLOGY.  
For about a year I have been testing stovaine as a local anaesthetic for operations on the nose, throat, and ear, in accordance with the request of the Cocaine Research Committee. On the whole it has proved very satisfactory indeed.

In fifty cases of cauterization with the electric wire anaesthesia with 5 per cent. stovaine was employed. The operation was quite painless: the drug produced less vasoconstriction than cocaine: there were practically no systemic effects and no toxic symptoms, and there were less after-effects than with cocaine, which gives a certain feeling of "cold" afterwards. For cauterization stovaine had all the good qualities of cocaine without the bad ones.

In fifteen tubular operations 10 per cent. stovaine was employed. The operation was painless, but there was more bleeding than with cocaine, though this could be controlled by mixing with adrenaline. There were no toxic effects, but the patient was more apprehensive, cocaine tending to diminish the dread of the operation. Thus stovaine, though quite satisfactory for these cases, was less so than cocaine.

In ten septum operations 10 per cent. stovaine was used,

mixed with 1 in 2,000 adrenaline. The mucous membrane anaesthesia was equal to that produced by cocaine, but the deeper bone was more painful. There was more bleeding, but no toxic effects. The "buck-up" effect of cocaine was greatly missed. Stovaine was thus not so satisfactory as cocaine for this major operation on the nose. In operations for nasal polypi and ethmoiditis the effects were just the same as in the septum operation.

Generally, with regard to stovaine anaesthesia in the nose my experience has been that it is perfectly safe and the surface anaesthesia is excellent; it is perhaps better than cocaine for purely mucous membrane work; the anaesthesia is slower and the vaso-constriction less; but it is on the whole not so satisfactory as cocaine for the major operations.

Twenty operations about the mouth and throat were performed under 1 per cent. stovaine. It seemed perfectly safe, there were no toxic effects; and the anaesthesia was good. There was very little vaso-constriction. For these cases it is much preferable to the injection of cocaine; but I do not think it is preferable to novocain, though little if any behind it.

In twelve cases the tonsils were removed under 1 per cent. stovaine. The anaesthesia was good, but there was much more bleeding than with novocain, and it was therefore not so satisfactory for this operation.

As a laryngeal spray for performing minor operations I used a 5 per cent. solution of stovaine, with excellent result in the three cases—one a papilloma and two foreign bodies.

On the whole, therefore, I consider that stovaine should have as big a place in the world of local anaesthetics as cocaine and novocain, more especially in minor throat and nose operations.

the London Hospital.

### THE EPILEPSIES.

Is epilepsy ever really idiopathic? This is a question which has been lurking in a nebulous state in my mind for years past. Recently I have had two cases bearing on this, where the apparently idiopathic condition has proved to be really secondary to a local irritation or lesion.

#### CASE I.

A young lady, aged 18, had had for two years bad attacks of twitching of the left side of the mouth and nose and indistinct exhausted sensations at irregular intervals, almost always after reading for a long time. Expert investigation of eyes and antrum gave negative results. The antrum was investigated, as I had detected signs of pain on pressure of the second left upper bicuspid. A skiagraph of the upper jaw showed a thickening of the root of this tooth. On extraction it was found to have a slight exostosis, and there was some chronic inflammation of the periosteum and pulp. The tooth was extracted over twelve months ago, and there has been no recurrence of the attacks; the patient is healthy in every way.

#### CASE II.

A married woman, aged about 46, with one grown-up daughter, two years ago had a severe and prolonged attack of multiple peripheral neuritis, beginning with symptoms simulating acute bulbar paralysis. She is abstemious and a careful liver in every way. The paralytic symptoms gradually disappeared under treatment. The main active drugs given were an alkaline mixture containing potassium iodide and bromide, with a little free iodine (iodide, iodate, and free iodine were formed in the stomach). There were no signs, stigmata, or any suspicion of specific disease. The daughter is perfectly healthy and normal, and above the average in mental development. Since this patient lost the symptoms of peripheral neuritis she has had frequent attacks of what appears to be typical petit mal, and once I had an opportunity of seeing her in a typical grand mal fit. She always has an aura, referred to the epigastrium, just preceding the fit. She is not unconscious in these fits, but in a sort of semi-delirious state (except in the one grand mal attack).

These two cases give me my peg on which to hang my question—Is epilepsy ever really idiopathic?

Flackwell Heath, Bucks.

## Rebuelus.

### EARLY SCIENCE IN OXFORD.

OXFORD is fortunate indeed in the ability and enthusiasm of Dr. R. T. GUNTHER, Fellow of Magdalen College, whose *Early Science in Oxford*<sup>1</sup> forms a valuable and generously illustrated record of the great men of the past. The first instalment, on chemistry, was reviewed in our columns five years ago (1921, ii, 708), and we were then warned that the issue of the remaining parts must await a longer list of subscribers. Fortunately this appears to have been effected, for last year Volumes III and IV appeared, "printed for the subscribers," and now a further volume, *Early Medical and Biological Science*, extracted from *Early Science in Oxford*, has been brought out without plates at the request of friends, who have expressed regret that the cost of the complete work puts it beyond the reach of a large number of students for whom it was written. This additional volume, which reproduces the earlier pages of Volume III, deals first with medicine in two chapters (early and in the seventeenth century and after), and then with anatomy, physiology, zoology, and geology; although it does not contain the beautiful plates of the original, it is illustrated by 47 figures, several of them occupying the whole page, and is of special interest to students of medical history.

The original statutes of the University (circa 1325) accorded an honourable status to physic and reckoned those skilled in medicine as more learned than others, since they are entrusted with the "cure of the sick, the perils of death, and the ordering of life," and it is therefore directed that great care must be exercised that only competent persons be allowed to practise or incept in that faculty. The first known lecturer on medicine at Oxford was Nicholas Tynchewyke or Tingewick (obit 1324), who is not noticed in the *Dictionary of National Biography*, but cured Edward I of his illnesses; it is also recorded that he rode forty miles to see an old woman who cured jaundice by administering the lice of sheep bruised and compounded with honey and water (hydromel), and gave her a sum of money for instructing him in the cure. It is interesting to learn that John of Gaddesden prophetically gave urea as a diuretic some centuries before its usually recognized discovery. The debt of medicine to Robert Boyle, which is perhaps hardly recognized to its full extent, is shown to crop up in unexpected directions, such as his advocacy of simple remedies instead of elaborate mixtures and the invention of the ammoniated quinine which so many patients who have suffered from influenza have cause to remember. There is much about blood transfusion at Oxford in the time of Lower, and, as is usual in these volumes, the reader finds new data. In the first half of the nineteenth century medicine was in a state of suspended animation, and in spite of a latitude in the choice of subjects, ranging from the botany of Virgil to a knowledge of volcanoes, allowed to candidates for the D.M. degree, there were not forty men on the books of all the colleges who had the right to put B.M. or D.M. after their names. The history of the Ashmolean Museum, which is finely represented in the frontispiece to the fourth volume, is set out in Volume III; its contents were given to the University by Elias Ashmole, "Mercuriophilus," who in turn had received its rarities from John Tradescant, junior (1608-62), though not without much trouble with his widow.

Volume IV is appropriately introduced by the Vice-Chancellor, who is also the Warden of Wadham, in a few words on the early association of his college with the Royal Society which grew out of the Philosophical Society of Oxford, the subject of this attractive volume. The Minutes of the Oxford Society for 1683 to 1690, reproduced from the manuscript in the Ashmolean Museum, are here

<sup>1</sup> *Early Science in Oxford*, vol. iii, Part I, *The Biological Sciences*; Part II, *The Biological Collections*. (Demy 8vo, pp. xii+564; 64 plates, 72 figures); vol. iv, *The Philosophical Society*. (Demy 8vo, pp. viii+259; 8 illustrations.) By R. T. Gunther. Oxford: Printed for the Subscribers, 1925. *Early Medical and Biological Science* extracted from *Early Science in Oxford*. By R. T. Gunther, M.A., LL.D., F.L.S. London: Humphrey Milford, Oxford University Press. 1926. (Demy 8vo, pp. 246; 47 figures. 7s 6d. net.)

printed for the first time; they contain many curious medical items, some of which may anticipate later observations: in the Minutes of May 13th, 1684, there is a record of a thermometer three inches long "which serves to show ye duration, increase, and Diminution of feavors"; the present short clinical thermometer, it may be recalled, was introduced by the late Sir Clifford Allbutt in 1867. The following memorandum occurs on a page headed "Cases of Appendicitis," a disease so named in 1886 by R. Fitz of Boston, Mass.: "The Society was informed by Mr. Musgrave that in the dissections of two persons, who died not many yeares since in Oxford of Consumptions, the Intestinum Coecum had these things remarkable in it; in one of them it was quite dried up, and grew fast to the peritoneum: in the other it was much leese, than usually it is." Possibly the first was the result of past appendicitis. The first case of acute appendicitis unearthed by Kelly and Hurdon was in France by Mesliver in 1759, and was associated with a pin in the appendix; while the first case reported in this country has previously been considered to be that recorded by James Parkinson (of Parkinson's disease) in 1812. Dr. R. Plot of Magdalen Hall, of whom there is a very charming portrait, was a regular attendant at the Philosophical Society, and in 1685 described a case which arouses a suspicion of acromegaly, though this is not suggested by the editor.

These volumes are an inexhaustible mine of information, and our gratitude to Dr. Gunther for revealing them in such a pleasant form is sincere.

#### MASSAGE AND THERAPEUTIC EXERCISES.

DR. KIRCHBERG, reader in massage and curative exercises in the University of Berlin, has issued the first volume of a manual<sup>2</sup> on these subjects, together with a supplementary volume on their relationship to physical or beauty culture.<sup>3</sup> In this first volume the history, technique, and effects of massage and manipulative and health exercises are discussed and described. The second volume will deal with these subjects in their application to the different organs and systems of the body, and will include chapters by gynaecological, surgical, ear, nose, and throat specialists and others. The fundamental principle, which the author insists upon throughout, is that a qualified medical practitioner should advise and control the work of masseurs, masseuses, surgical manipulators, and physical instructors generally. Different types of physical development demand different forms of exercises, and different diseases different forms of massage and manipulative treatment. The connexion, therefore, between the doctor and those who practise these arts must be close, if injurious results are to be avoided and quackery checked. Dr. Kirchberg even goes further and considers that the doctor should also be consulted in the use of massage and physical exercises for the preservation of beauty; as he very truly remarks, good looks depend chiefly on good health. From his point of view massage and physical exercises are simply instruments in the armamentarium of the surgeon and physician.

In the opening section of the first volume a concise account is given of the practice of massage in ancient times, in China, Greece, and Rome; and in the early and late Middle Ages. A special account follows of the influence of Ling, who flourished between 1776 and 1839 and who is regarded as the father of modern therapeutic exercises and the originator of the Swedish school that has spread its influence throughout Europe. The development of massage and physical training in Prussia and Germany since 1840 is described, together with a general history of the literature and progress of the subject during the past century.

The section on technique contains a detailed and illustrated description of the different procedures in massage, and the manipulative and physical exercises applicable to the movements of limbs, joints, and muscles, together with numerous practical details of clothing and the position

of masseurs and patients, the temperature, equipment and lighting of massage rooms, duration of the manipulations, and so on. The final section deals with the effects of massage and exercises on the body generally and on the different organs and systems; and concludes with a bibliography of general history and of works on the technique and effects of massage and therapeutic exercises.

The greater part of the supplementary volume is taken up with the physical culture of children and schoolgirls, and with face massage, but its final chapter on the preservation of good looks in advancing years is of much interest. The author impresses on us the advantage of continuing, after retiring from business or official life, some occupation or other, preferably in the open air; and not giving way to habits of inactivity and indolence. There is no reason why older men should not do gymnastic exercises. He recommends golf as a sport, and notes that there are golf courses now at most health and seaside resorts. There is also much good advice to women in this chapter and in the pages of the volume generally. Women are warned against painting their faces, which only makes them repulsive to sensible men. But in condemning the modern fashion of cropping the hair as likely to cause baldness, and of shaving the armpits as hygienically and physiologically objectionable, the author will find many dissentients. His views, however, on exercises and sports in the physical culture of women are sound and in accordance with present-day teaching. He approves of light clothing and short skirts, but considers that much of their value physically is lost by the wearing of high-heeled shoes. We can recommend both the manual and its supplement, not only to the medical profession, but to all who are interested in the subjects with which they deal.

#### THE LUMBAR REGION AND PELVIS.

THE publication of the third volume of Professor Grégoire's treatise on the medical and surgical anatomy of the abdomen<sup>1</sup> brings the work to a completion. The regional classification adopted may to some appear somewhat arbitrary, but is amply justified in the course of the author's exposition. Volume I, the second edition of which was published in 1922, dealt with the thoraco-abdominal region; Volume II, which appeared in the same year and was reviewed by us in 1923 (vol. i, p. 575), dealt with the subthoracic region of the abdomen, and the present is concerned with the lumbar region and pelvis. In expounding the subject the author first describes, as regards the lumbar region, its external form, then the structure of its wall—skeletal, fibrous, muscular, and tendinous—and its vessels and nerves. Then follows a chapter on the weak spots of the wall—the lumbar groove bounding the mass of the erector spinae muscle externally, Grynfelt's space situated at the upper end of that groove, and the triangle of Petit. Next the compartments of the region are described—an upper or thoracic and a lower or renal compartment; and a section is added, discussing the best routes of surgical access in the lumbar region. A detailed description of the kidney and suprarenal gland, their relations, fixation, and vessels, and of the urinary excretory channels, completes this portion of the work. The account of the pelvis is on similar lines, but of greater length corresponding to the greater complexity of the subject; it includes matters of special interest, such as the sacro-iliac articulation and its mechanical principles, the floor of the pelvis and the sphincter apparatus of the lower outlet, the static relations of the uterus, and the fixation and relations of the prostate.

A mere summary of the contents of the volume, however, gives but a very imperfect conception of its merits. One very obvious feature is that the work is first hand and original from beginning to end, and after its perusal we have no difficulty in accepting the author's statement that he has written of what he has seen and expounded the facts according to his own comprehension of them. The book reads as if the author were handling the parts as he

<sup>2</sup> *Handbuch der Massage und Heilgymnastik*. By Dr. Franz Kirchberg. Leipzig: Georg Thieme, 1926. (Sup. roy. 8vo, pp. viii + 279; 71 figures, 19 plates. M.14.50, bound M.16.50.)

<sup>3</sup> *Massage und Gymnastik im Dienste der Kosmetik*. By the same author and publisher. (Post 8vo, pp. v + 99; 25 figures. M.3.90.)

<sup>1</sup> *Anatomie Médico-Chirurgicale de l'Abdomen. III: Le Lomboire de l'Abdomen et le Petit Bassin*. Par Raymond Paris: J. B. Baillière et Fils. 1926. (Roy. 8vo, pp. 204; 85 fig. plates. 2 dollars.)

wrote, and this gives great freshness to the description as compared with those textbooks which consist largely of excerpts from other writers. Again, the author possesses the gift of verbal delineation in an unusual degree, and this, added to the natural clarity of the French language, renders his book eminently readable. It cannot be said that the majority of books on descriptive anatomy lend themselves readily to 'continuous' reading; as works of reference on special points or even taken in limited sections they are acceptable, but their continuous perusal involves exertion. Professor Grégoire, on the other hand, blends his facts with great skill, so that his descriptions almost assume the form of pure narrative. Among the original observations contained in the volume some do not appear to differ essentially from the teaching adopted in this country. Thus the excellent account given of the mechanics of the sacro-iliac joint is stated to differ from the accepted classical description, although it appears to agree in essential particulars with that of the best English writers on anatomy. On certain points, however, a discrepancy is manifest. Thus in dealing with the perineum the author refers to the current teaching that the triangular ligament forms part of the anterior wall of the pelvis, much in the same way as the obturator membrane helps to form its lateral wall. This, he points out, cannot be true of the female pelvis, for in it the hinder part of the so-called triangular ligament is deficient in the middle line and does not pass across from one limb of the osseous subpubic arch to the other behind the vagina, as is figured in some of our leading English textbooks, but terminates on each side at the posterior extremity of the bulb of the vestibule to which it is attached. Were the hinder part of the ligament continuous across the bony arch, the vagina would pass through a rigid and inextensible fibrous membrane. Professor Grégoire describes each bulb in the female as being connected with the ischio-pubic ramus of its own side by a suspensory ligament, and says that this arrangement is modified in the male by the two ligaments coming together and fusing in the middle line of the perineum. The book contains numerous full-page illustrations, almost all of them original and serving admirably to explain the more complicated relations.

Professor Grégoire is to be congratulated on the completion of a fine work.

### OBESITY.

It is some years since a work solely devoted to the subject of *Obesity*<sup>5</sup> has appeared, at any rate in this country, so that Dr. LEONARD WILLIAMS is able to present the subject with the new knowledge now available about the endocrine glands. Etiologically he divides obesity, which he has no hesitation in stigmatizing as an unnatural condition inimical to bodily health and mental efficiency, into the alimentary, in which connexion he preaches the dogma of temperance in eating with much force and many apposite illustrations, and the endocrine, of which the historical cases of Napoleon and Daniel Lambert are held to be examples. There are five chapters and the same number of short appendixes, the latter giving weight tables and diets. Some of the chapter headings are sprightly—for example, the "Bantlings of Obesity," in which the early stage of the condition is discussed, and "Eve," which is concerned with the fat members of the female sex. In the last chapter, entitled "Counterchecks" on treatment, dietetic restrictions, including fasting, though not going all the way with Guelpa's purgative methods, are outlined with a firm but light hand. "Unfired" or uncooked foods are regarded as essential, even in almost all forms of endocrine obesity, for it has been said that the vitamins are to the endocrines what the endocrines are to the economy as a whole. In describing the case of Mr. Banting, who in 1862, on consulting a Mr. William Harvey for deafness, was shrewdly diagnosed as owing this to his obesity, and accordingly was treated by diet with benefit for both affections, Dr. Leonard Williams praises the insight of the otherwise unknown adviser. The tradition

that a rapid loss of weight is inadvisable is treated with scant respect, but the thyroid treatment is carefully discussed, and small doses recommended initially; the combinations of thyroid with parathyroid and pituitrin receive attention.

As the commonest form of obesity is brought about by an excess of alimentary intake over muscular output, increasing the amount of exercise would appear to be a remedy; but it does not always succeed in arresting the corpulence—indeed, some patients, it is said, do better when kept in bed until, by dietetic means, the habit of storing up food in the form of fat has been overcome. General physical exercise, it is thought, should be advised to the obese only with great care, as it may cause considerable strain on the heart, lungs, and excretory organs. Raising the body temperature reduces obesity, and it is in this way that thyroid extract is held to act; whereas iron acts indirectly by increasing the oxygenating properties of the red corpuscles.

### HANDBOOK OF DISEASES OF WOMEN.

The appearance of an eighth edition of *The Diseases of Women*,<sup>6</sup> by BLAND-SUTTON and GILES, is a gratifying indication of the continued popularity of what is by now becoming an old book.

The first edition was published in 1897; thirty years or thereabouts is a long span of life for a medical textbook, and is proof of the vital excellencies of the work. In this edition little alteration has been made, and, as we reviewed the previous edition somewhat fully, little need now be said. The authors have thought it advisable to introduce two new chapters, dealing with radio-therapy, and with the physiology and therapeutics of the endocrine glands in their relation to gynaecology. The former is a useful synopsis of the opinions of various experienced clinicians, including the authors, but the latter is a brief review of an exceedingly complex subject, which on that account is perhaps not quite up to the level of the rest of the book. Considerable space has been devoted to myomectomy for fibroids, which the authors think is a mode of operation which is liable to be overlooked. As to this there is room for differences of opinion, but it is needless to say that the description of the operation is as satisfactory as the rest of the operative section of this well known textbook.

### AMPUTATION.

Dr. ORR of Kansas has produced a monograph<sup>7</sup> which should be useful to those surgeons who, without much experience, contemplate the performance of an amputation, but he has hardly attained the ambition of his title. The methods described are modern in the sense of being in present use but not in the sense of being new. Most of them have stood the test of time. A chapter is devoted to Vanghetti's cineplastic method, but the author evidently has but little personal experience of it. In this country it has been practically abandoned after a fair trial, like some other methods which were vaunted during the great war, but which he does not mention. The only osteoplastic amputation described is the Stokes-Gritti, a proceeding which to many surgeons familiar with thigh stumps does not seem to be justified by any advantages over an ordinary amputation.

The illustrations are numerous and clear. This book may answer a demand for such a work in America, but in this country the practical handbook<sup>8</sup> of MARTIN HUGGINS will probably, and justly, be preferred, as although it is not a textbook on amputation it deals with practical results and indirectly points out the best methods of operation. Dr. Orr acknowledges his debt to this work among others.

## NOTES ON BOOKS.

SINCE Dr. Budin established in Paris in 1892 the first infant welfare centre, there has been so rapid a multiplication of such places in this country that it is almost certain every medical practitioner must have come into contact with them either directly or indirectly. That everyone understands the purpose of these centres and their correct management is not equally certain. To inform those who have not this knowledge, and to assist those who are embarking upon this work for the first time, Dr. CHODAK GREGORY has written a little book entitled *Infant Welfare*.<sup>9</sup> The first chapter is devoted to the management of a welfare centre, with a brief reference to the Acts dealing with this subject. The second chapter deals with the general management of the child, and the kind of advice which should be given to the mothers in order to prevent ailments and disorders. A few discriminating remarks are given on the use of the "comforter." Dr. Gregory's championship of its wisely restricted use will probably provoke discussion. Doctors who have an intimate personal knowledge of infants, and have given thoughtful observation to this much abused object, will doubtless support the author. Chapters III and IV are résumés of modern methods of breast-feeding and artificial feeding. The other chapters are devoted to a brief consideration of food, stools, vomiting, prematurity, rickets, rashes, and pyrexia. The final chapter gives a short account of the infant mortality rate in this country. The author states in her introduction that the "welfare doctor" is there to prevent disease and not to cure it, but her book can nevertheless not escape the criticism that much space is devoted to treatment. The real function of such a doctor should be to prevent illness by education of the mothers, and when any departure from the normal occurs in the infants they should be referred to a paediatrician for treatment.

The first edition of Professor CHRISTIANSEN's book on cerebral tumours<sup>10</sup> was reviewed in these columns some three years ago. A second edition has now appeared in which, while the general form has been retained, the text has been emended and brought up to date. As a contribution to clinical neurology we have nothing but praise for this book. The subject is throughout presented in a style that is vivid, easy to read, and abounding in graphic clinical descriptions. The reader will find much fresh material in the chapter dealing with tumours in the region of the optic chiasma. A new and valuable chapter also is that on uncertain diagnosis. We find no mention of the modern method of diagnosis by ventriculography, an omission which some will perhaps approve. The book really consists of a series of clinical lectures, where the varieties of tumours are described and discussed according to their topographical distribution in the brain. It may be read with advantage by neurologists and students alike.

The second edition<sup>11</sup> of *Ear, Nose, and Throat Nursing*, by Dr. HARDIE NEIL, has been revised and considerably enlarged, and thus rendered more useful to hospital medical officers who are concerned with lecturing to nurses, and also to general practitioners. This book is well illustrated, and should be popular.

In a small book entitled *Electrothermic Methods (Desiccation and Coagulation) in the Treatment of Neoplastic Diseases*,<sup>12</sup> Dr. J. D. MORGAN gives a short account of electrothermic procedures, including the methods of producing desiccation and coagulation. With the aid of numerous illustrations he describes the types of apparatus employed and the various indications for these forms of treatment. The book is written from the practical standpoint, and gives a simple description of a form of treatment which has received a good deal of attention during the last few years.

Were it not that Mr. GEORGE POPOFF states explicitly that his book is not an anti-Bolshevist pamphlet, it might well be thought that his "murky and horrible" descriptions in *The Tcheka*<sup>13</sup> were propagandist. To anyone in Western Europe it must seem incredible that a body such as the Russian political secret police should exist in a country which claims to have established a higher system of government than the

world has ever known. According to Mr. Popoff, the Tcheka is a State within a State; so that the Government in the Kremlin with which Europe has relations is overshadowed by the Government in the Lubjanka, which is making illusory all agreements with the Soviets. The frontispiece to the volume is a portrait of the head of this organization, Dshershinsky, who has since died in circumstances which are thought, even in Russia, to call for explanation; it is an unpleasant, crafty face, although Mr. Popoff describes it as ordinary and almost good-natured. Against this person the comparative moderation of Tchitcherin, Lunatcharsky, and Radek were apparently of no avail; consequently a system of terror, the author says, goes on within the Lubjanka, where interrogatories are carried on by weird savages and boors, while more cunning traps are set for prisoners by a smooth-tongued ruffian Artusoff. The interrogatories not infrequently end at the hands of one of the guild of executioners, which is apparently a very well paid body in this Communist country, Russia. The only excuses that Mr. Popoff can make for this outrageous state of affairs are that such actions are natural to the Asiatic Tartar, and that the Tcheka is simply an inheritance of the Oclhrana, or secret police of the tsars. Mr. Popoff anticipates an emphatic denial of the truth of this book from Moscow, where "the great Asiatic art of lying is admirably understood." Certainly the story takes one's breath away. Its truth can never be settled until this land of a new heaven and earth opens its doors to strangers and allows free intercourse with its neighbours.

## PREPARATIONS AND APPLIANCES.

## A Tonsil Snare.

Mr. D. MALLAM (Redhill) writes: Messrs. Mayer and Phelps have recently made for me a tonsil snare which combines the haemostatic advantages of Beck's instrument with the leverage and ease of application of F... 's sturdy and all parts are open to inspection. It is simple in action and devoid of... The end pieces are similar to those used in Beck's instrument, may be of any

sized aperture, and are readily attached at r. After engaging the tonsil within the aperture the wire loop is tightened by approximation of the finger ring A to the handle B until the pedicle of the tonsil is tightly gripped. The revolving nut C is spun up into position against the body of the instrument B by means of its arms. The wire loop is then gradually tightened further by slowly turning up the nut C until the tonsil is separated.

## A Combined Skioptometer and Phorometer.

Lieut.-Colonel E. A. R. Newman, I.M.S.(ret.), who is ophthalmic surgeon to the Stamford Infirmary, sends a note on an automatic skioptometer which he has found very convenient and expeditious in use. The apparatus has been designed and made by Messrs. Clement Clarke of 16, Wigmore Street, W.1.

An endless chain of forty spherical convex and concave lenses is mounted on a vertical triangular frame, made of aluminium. The lenses are rotated through the sight holes by a milled wheel attached to an extensible rod. An indicator below the sight hole shows the power of the lens in use, and powers above five diopters are obtained by mounting an additional lens on a stud attached to the frame. At the suggestion of Colonel Newman Mr. Clarke devised means whereby the apparatus can be used as a phorometer. Twelve concave cylinders are mounted in a metal disc suspended in a bracket, which can be swung into position and clipped firmly against the sight hole. A fixed pointer shows the orientation of the axes of the cylinders on a scale engraved on the milled wheel which revolves the disc. The exact setting of the axis of the cylinder enables the measure of correction of the vision to be quickly arrived at, and any combination of sphericals with an astigmatic error of not more than 3 D., or any degree of astigmatism with a maximum or minimum error of 5 D. in hypermetropia and myopia respectively can be provided for. For refractive errors of a higher degree an additional spherical lens can be held in front of the apparatus.

In Colonel Newman's opinion the instrument, which is a product of British brains and workmanship, compares most favourably with far more expensive phorometers of foreign manufacture.

## Differentiation of Bacteria.

Messrs. Burroughs Wellcome and Co. (Snow Hill Buildings, E.C.1) ask us to inform medical bacteriologists that they are in a position to supply sodium salts of the following organic acid: d-tartaric, l-tartaric, meso-tartaric, citric, fumaric, and mucic, now used in the differentiation of bacterial types in which "sugar reactions" are untrustworthy or fail.

## THE STATE OF THE PUBLIC HEALTH.

## SIR GEORGE NEWMAN'S REPORT FOR 1925.

[Concluding Notice.\*]

## THE INSURANCE MEDICAL SERVICE.

THE total population of England and Wales in 1925 was 38,890,000, and 13,695,000 persons were entitled to medical benefit under the National Health Insurance Act. The number of insurance practitioners was 13,827, and the average number of persons on a practitioner's list was 957. The total cost of medical benefit in the year was £8,280,300, of which approximately £6,411,138 was devoted to the remuneration of doctors.

*Extended Medical Benefit.*

A comprehensive scheme for the provision of consulting, nursing, and laboratory services was prepared in 1914, but was held up by the war. It will be remembered that in the report of the Royal Commission on National Health Insurance, issued last March, the need of such services was fully recognized, and it was recommended that there should be supplied expert medical advice and treatment with laboratory services. Sir George Newman considers that this new system of "expert out-patient services" would include advice in diagnosis and treatment and the provision of specialist treatment necessitating special equipment and skilled assistance such as that of masseurs or electricians. He thinks that the system should be built up, not as a supplement to the existing out-patient work of the hospitals, but as an independent scheme, organized effectively throughout the country, and furnishing the closest consultation and reciprocal communication between the general practitioner and the specialist. An obligation would be laid on the practitioner to refer a patient for specialist assistance, when necessary, and to supply an account of the clinical history and present condition of the patient; the specialist would be required similarly to report to the practitioner and to give advice about any further treatment required. This obligation, Sir George Newman thinks, would have a beneficial influence on the practitioner in defining his ideas and in drawing his attention to any possible defects in his previous conduct of the case; similar services would again be rendered by the specialist's report. Such co-operation would thus operate as a valuable form of post-graduate instruction, and would therefore be welcomed by isolated practitioners, the resulting educational benefits being extended to general medical practice outside the domain of insurance work.

*Obligations of the Insurance Practitioner.*

The range of the insurance practitioner's obligations is discussed at some length. The insured population has statutory rights to receive all treatment, surgical or otherwise, which is covered by the contract of medical service. When an insurance practitioner claims that an operation or other service which he has actually performed is outside his insurance obligation by reason of its having necessitated special skill and experience beyond that possessed by general practitioners as a class, the onus is thrown upon him to establish the fact that he possesses such abilities. The regulations provide that he must prove that he has held appointments, or engaged in academic or post-graduate work affording opportunities for acquiring the skill and experience, and has also had recent practice of the special kind of treatment in question. Alternatively he must show that he is generally recognized by other local practitioners as having such special proficiency. Lists are given of such disputable cases in which decisions were given by referees or reached by agreement between the local medical and insurance committees. Sir George Newman considers that the procedure for dealing with these cases, which has been in operation for thirteen years, has stood the test of time, and he adds the following words:

"I think it is true to say, however, that insurance practitioners as a body are not disposed to take a narrow view of the range of their obligations: and it is known that there are practitioners who habitually and without charge render to their insured patients services which, if the question were raised, would probably be held to be outside the scope of medical benefit."

\* Previous notices were published in the JOURNAL of September 11th, p. 554, and September 18th, p. 555.

*Regional Medical Staff.*

The regional medical staff was appointed in 1920 and enlarged in 1925; it now consists of five divisional medical officers, thirty-three regional medical officers, and thirteen deputy regional medical officers. In addition to these, from time to time part-time medical officers are engaged temporarily. During the year under review 201,832 cases were referred to it for decisions as to capacity for work, and 2,256 for a second medical opinion as to the possibility of expediting the restoration of a patient's working capacity; the corresponding figures for the previous year were 183,846 and 2,270. The great majority of these cases were referred by approved societies; and Sir George Newman expresses regret that medical practitioners have not made greater use of the facilities provided for obtaining a second medical opinion. The number of practitioners visited by the staff in connexion with the inspection of the registers of dangerous drugs was 5,197 and the number of hospitals was 54.

## FOOD EXAMINATION.

In a short reference to the importance of vitamins, Sir George Newman mentions the number of food preparations on the market for which a high vitamin content is claimed. He adds that recent research work points to the possibility that chemical tests may be devised to estimate approximately vitamin contents, in which case such food preparations could be brought within the operation of the Sale of Food and Drugs Act. He refers in some detail to the problems associated with tuberculous milk, and suggests that local authorities should now reconsider their responsibility for examining samples of milk for tubercle bacilli. In many rural districts this is not practised, and county medical officers are recommended to secure co-ordination and the adoption of some common procedure in the areas under their control. Although graded milk does not yet constitute more than about 1 per cent. of the total milk consumption, yet grading is important in that it provides a high quality milk for a section of the population, and exerts a valuable educational influence on all milk production. Graded milks are, moreover, increasing in popular favour; thus the producers' licences for "Certified," "Grade A—Tuberculin tested," and "Grade A" milks were respectively 94, 98, and 176 in 1925, as compared with 71, 61, and 92 in the previous year, while there was a corresponding increase in retailers' licences. The issue of the Public Health (Preservatives, etc., in Food) Regulations in August, 1925, secured that such staple foodstuffs as milk, meat, bacon, butter, margarine, eggs, and cream should be free from preservatives, and that the presence of permitted preservatives in sausages, sausage meat, coffee extract, pickles, and sauces should be declared.

## POOR LAW MEDICAL SERVICE.

It is noted with satisfaction that the practice of appointing consultant medical officers to Poor Law infirmaries is extending, and that increasing use is being made of their services, which in some cases include the actual treatment of patients under the administrative supervision of the medical superintendent. Co-operation between the medical officers of Poor Law institutions and tuberculosis officers is more complete, and it is suggested that there might well be more general co-operation also with health authorities in dealing with epidemic and venereal diseases. The total number of Poor Law infirmaries approved as training schools for nurses by the General Nursing Council at the end of 1925 was 137, 17 having been added during the year. The difficulties attending reduction of the working hours of nurses are mentioned, and it is suggested that any further decrease should be effected by lengthening the yearly leave rather than curtailing the number of daily hours of work. Sir George Newman emphasizes the special care necessary in dealing with aggregations of infants to prevent intestinal and respiratory infections, and recommends the construction and administration of nurseries on sanatorium lines, the treatment of young infants in quite small groups, the isolation of infants together with their attendants in the event of acute catarrh, and strict antiseptic precautions in dealing with individual infants and the preparation of their food.

## INTERNATIONAL HEALTH.

## EXPANDING ACTIVITIES OF THE LEAGUE OF NATIONS.

[FROM OUR CORRESPONDENT AT GENEVA.]

SOME interesting discussions took place last week in the Third Committee of the League of Nations Assembly—the committee which, under the chairmanship of Mr. Desmond Fitzgerald, of the Irish Free State, is charged with the consideration of the health and other technical organizations of the League.

The first contribution of a German delegate was by Baron von Rheinbaben, a member of the Reichstag, who said that Germany, like other countries, recognized the importance of international health organization. German operation in this field had begun directly after the war, and had not awaited Germany's entrance into the League of Nations. Germany, now a member of the League, would naturally be all the more ready to place her great experience in medical and pharmacological matters at the League's disposal. German medical officers had already participated in health expeditions under the League's auspices. At present an international committee was studying the sanitary conditions in German ports, and at the same time a German was co-operating with British, French, Belgian, and Portuguese experts on the sleeping sickness commission now in Uganda. Various proposals mooted for the extension of the health work had Germany's full sympathy, especially a proposal that the League should take physical education and school hygiene within its province, and he reminded the Committee that Germany had a non-official organization, called the "high school for physical culture," which existed to promote athletics, and it was due to this organization that Germany had gained its recent prowess in the playing field.

*Physical Culture and School Hygiene.*

The suggestion that the League Council should consider the question of physical education and school hygiene was made by the Czecho-Slovakian delegate, Dr. Vererka, who said that his country possessed one of the most powerful organizations for physical culture in the shape of the Sokols, a civil association which works in conjunction with the army authorities for the physical welfare of the troops. The Sokols have one million adherents in Czecho-Slovakia and carry out a vast programme of physical culture. The proposal to ask the Council to consider the importance of physical culture as a means of preventing disease was supported by the delegates for Austria and for Japan, the latter gentleman referring to the great strides which had been made in school hygiene in his country during recent years. On the other hand, one of the Canadian delegates, the Hon. Philippe Roy, who is a medical man, while recognizing the benefits accruing from the physical instruction of youth, did not think this work to be of a sufficiently international character to warrant an appropriation of money by the League. It was decided to refer the proposal to the permanent Health Committee for consideration, together with certain other proposals, one by the Uruguayan delegation, calling for a study of nutritional problems in relation to race improvement, and another by the Cuban delegation, to make an international investigation of the problems of eugenics in a wider sense than the question of infant mortality and the protection of children, into which the Health Committee is already inquiring.

*Epidemiological Intelligence.*

A good deal of discussion centred round the newly formed bureau for epidemiological intelligence at the Singapore, which is the first extension of the League's activities in the Far East. Each week telegraphic information regarding the health conditions in upwards of eighty parts of Asia, Australasia, and the east coast of Africa is collected and disseminated, telegraphically to Eastern health administrations, and by post from Geneva to Western. The Japanese delegate pointed out that the Singapore bureau was supported for a limited time by the Rockefeller Foundation; when these allocations ceased he hoped that the League would assume the entire burden.

An Indian delegate also spoke of the extreme usefulness of the bureau, and several other speakers urged its importance, not only as a centre of information, but as earnest of the League's interest in Far Eastern conditions. The proposal that provision for the expenses of the bureau should be made in the budget of the League was accepted, subject to the additional credits not bringing the budget of the health section above the maximum at which it was stabilized last year. The last Assembly voted 988,000 Swiss francs (nearly £40,000) as the budgetary maximum for health services, but as the entry of Germany brings to the League another important national contribution, it was agreed that a further credit of 25,000 francs might be inserted in the budget without transgressing the spirit of last year's resolution.

*Malaria Commission.*

Dr. Lutrario of Italy spoke of the value of the malaria commission which had been studying the incidence of the disease and the measures taken in various countries for its control. A travelling commission had studied the preventive measures taken and the importance of regional and local conditions. This work, he said, had included the study of conditions in great river deltas, the effect of land reclamation and drainage, and climatological and meteorological conditions as affecting the intensity and spread of the disease. He referred specially to the importance of the studies made in India, where, by a careful study of the conditions, meteorological and other, it was possible to foretell the probable intensity of the malarial troubles during the ensuing malarial season.

*Expenditure, etc.*

The actual expenditure by the League on health work in 1925 was 813,611 Swiss francs (about £32,500), but to this has to be added the sum received from the Rockefeller Foundation—730,521 francs (nearly £30,000)—in order to arrive at the total amount expended under the League's auspices. The amount estimated to be received in the way of Rockefeller benefactions in 1926 is 667,726 francs, and in 1927, 538,161 francs. The objects on which the Rockefeller grants are expended are the interchanges of public health personnel, the epidemiological intelligence service, and demographic and public health studies. For the two latter purposes the allocations for 1926 are the same as for 1925, but there is a progressive reduction in the amount expended on interchanges of public health personnel.

Many references were made to the exchanges of medical officers. The Japanese delegate said that during the past year the tours of investigation had extended to the Far East, and it had been possible for Japan to make the acquaintance of the director of the Health Section, Dr. Rajchman, and of twenty medical experts. Dr. Ramos of Cuba recalled the fact that the first exchange of medical officers took place at Havana, which was becoming a permanent centre for the exchange of information in Central and South America. The first pan-American congress on eugenics and on the physical and moral education of children will be held at Havana in February, 1927.

Other work proceeding under the auspices of the Health Section includes a special investigation of national health insurance in various countries, of the control of the manufacture and distribution of foodstuffs, and of the prevalence of trachoma. A tuberculosis commission is continuing its study of the causes underlying the decline in tuberculosis mortality. The epidemiological intelligence service continues to expand, and the monthly reports contain information regarding the prevalence of epidemic diseases and certain mortality statistics in 29 European, 17 African, and 16 Asiatic countries, and in Australasia. The Third Committee, in terminating its health discussions, decided to recommend the Assembly to record its satisfaction at the widening character of the health work of the League, especially the highly valuable and somewhat dangerous work of the international commission on sleeping sickness now working in equatorial Africa, and the close collaboration which has been established with the sanitary and medical authorities of Japan as a result of the interchange of officers and the conferences held in that country.

## British Medical Journal.

SATURDAY, SEPTEMBER 25TH, 1926.

## EMOTIONAL CHANGES IN DISSEMINATED SCLEROSIS.

THE current number of the *Journal of Neurology and Psychopathology*<sup>1</sup> includes an important study on the affective symptomatology of disseminated sclerosis by Drs. S. Smith Cottrell and S. A. Kinnier Wilson. The conclusions reached by the authors, which are based upon the neurological and psychological investigation of 100 consecutive cases of disseminated sclerosis of both sexes, have more than a theoretical interest, because it is considered that the emotional symptoms described are definitely characteristic of disseminated sclerosis, that they are primary or direct results of the disease processes, and that they are wholly independent of degree, duration, or clinical type. It is stated, indeed, that affective symptoms are more frequent than any single symptom of the neurological series (nystagmus, scanning speech, tremor, spasticity, etc.), and that they constitute diagnostic criteria of greater value than any neurological symptom-complex. This clinical contribution is thus of definite practical interest, and merits the attention, not only of the neurologist and psychiatrist, but also of the general practitioner, who meets with cases of disseminated sclerosis in both its early and late stages.

The authors found that the abnormal emotional reactions were exhibited in three directions—in changes of mood, in changes of bodily feeling, and in changes in emotional expression and control. In 100 per cent. of the cases an alteration in the prevailing mood of the patients was observed. In 63 per cent. there was an increased sense of mental well-being. The authors suggest the phrase "euphoria sclerotica" to indicate this common affective state of ease, tranquillity, serenity, happiness, or even gaiety in patients with disseminated sclerosis, and the phrase "dysphoria sclerotica" to indicate the feeling of mental unrest, disquiet, uneasiness, or unhappiness which was observed in 10 per cent. of their cases. In 25 per cent. an increased variability of mood was noted in which the patients were subject either to abrupt transitions from a mood of sadness to one of euphoria, or from euphoria to sadness. In two cases an indifferent and stolid reaction was recorded as a change in the emotional attitude since the onset of the disease.

The sense of physical well-being (eutonia sclerotica) which the authors discovered in 84 per cent. of their cases led them to the view that this must also be accepted as one of the fundamental symptoms of disseminated sclerosis. It was discovered in early and late stages of the disease, and was in some cases in striking contrast with the actual physical incapacity of the patients concerned. Thus a patient who was almost moribund when examined declared that physically she "felt all right," and was neither tired nor weary, but quite at her ease. In many instances the patients were themselves more than a little amazed at the apparent incongruity between their

sense of bodily ease and health and their actual crippled state. A similar though much more extreme eutonic state is, of course, common in general paralysis of the insane. Here, however, the patients actually believe themselves to be possessed of unusual physical power, and are unable to appreciate the fact that they are the subjects of a crippling physical illness. This lack of insight is in some measure due to the fact that there is considerable intellectual deterioration—a condition very rarely observed in patients with disseminated sclerosis. The latter feel well, but are conscious of the fact that they are suffering from a physical malady. Indeed, disseminated sclerosis is but rarely associated with psychotic symptoms. Thus, of 6,700 patients in the Manhattan State Hospital (1921) there were only three cases of disseminated sclerosis. In 84 per cent. of the patients an attitude of optimism about the future and their prospects of ultimate recovery, similar to that which obtains in advancing cachectic conditions such as pulmonary tuberculosis (spec phthisica), was observed.

The exaggeration and facility of outward expression of emotion in disseminated sclerosis is regarded by the authors as a symptom of immediate diagnostic value. Thus, when in a young person simple routine questions are responded to by gratuitous and uncalled-for smiles or laughs, disseminated sclerosis, it is suggested, at once becomes a diagnostic probability. In some cases, indeed, undue affective display was one of the earliest symptoms of the malady, before any somatic neurological sign had made its appearance. In only three cases was no emotional overaction present; in 71 per cent. the expression was "set" to smiles or laughter; it was "set" to tears in only 3 per cent.; and in 19 per cent. laughing and crying alternated. These emotional reactions occurred "in season and out of season"; under slight provocation, at the bidding of minimal stimuli, they made their appearance when there was obviously no warrant for them. In advanced cases in particular, when there is a serious defect of articulation so that the patient is unable to make himself understood, it is often difficult to know how far the uncontrolled emotional display is expressive of the actual mood of its subject. This problem was made the subject of a special investigation in this research, and it was found that in a large proportion of cases there was a definite and striking incongruity between the emotional content and its outward expression. Thus in one instance, while a depressed patient was recounting thoughts of suicide which she entertained, her face was wreathed in smiles and she frequently burst into uncontrollable laughter.

Apart from its purely clinical interest, this contribution would seem to add to our knowledge of the neuropathology of emotional disturbances. As regards the pathogenesis of the affective symptoms in disseminated sclerosis, it is considered that, like the somatic symptoms, they probably arise from invasion of the cerebral mechanisms by a toxic agent. More specifically, the abnormal emotional reactions are associated with the well known pathological fact that the disease almost constantly shows subependymal spread, and the relative conservation of the intellectual faculties with the relative conservation of the cortex. Evidence is also adduced which suggests that the affective symptoms are the outcome of the invasion of the paleocephalon by the morbid process. The interesting fact emerging from this research is that the alterations in the emotional life would seem to depend, not upon an alteration, either quantitative or qualitative, of the totality of the afferent impressions from

<sup>1</sup> The *Journal of Neurology and Psychopathology*, July, 1926, London: The British Medical Association. Published quarterly. Subscription 30s. per annum; single numbers 6s. 6d. net, post free.

somatic and visceral receptors, but upon a misinterpretation of these impressions due to a dynamic change in thalamic function, the sequel to toxic action. Briefly, the affective symptoms in disseminated sclerosis are probably attributable to disease of the emotional "centre" rather than to changes in organic sensibility, which are responsible, speaking physiologically, for mood changes in normal individuals.

Drs. Cottrell and Wilson suggest that the clinical data of disseminated sclerosis, so far as the affective sphere is concerned, may throw light upon the pathogenesis of the emotional phenomena of various psychoses and psychoneuroses, in which that sphere is definitely disordered. Such suggestions merit careful consideration, since the clinical resemblances between the affective symptoms described in this paper and those observed in some psychotic states are very striking, and it may be that they have analogous neurological determinants. As an instance, the curious dissociation between feeling, thought, and action (intrapsychic ataxia), which is so characteristic a feature of *dementia praecox*, may be cited. In such cases, as Kraepelin observes, "the patients laugh and weep without recognizable cause, without any relation to their circumstances and their experiences; and they smile while they narrate their attempts at suicide." The resemblance to the incongruous emotional reactions noted in disseminated sclerosis cases and referred to above is here very evident. It is useful also not only to compare but to contrast the affective disturbances in the biogenetic psychoses with those in disseminated sclerosis. In the latter, in spite of the presence of widespread disease of the central nervous system, the affective disturbances, though characteristic, are mild, and there is no disintegration of the personality. In the former, however, though there are no objective signs of organic disease of the central nervous system, the affective symptoms are severe, and there are profound disturbances of the personality as a whole. Though cerebral mechanisms are no doubt involved in psychoses, the biological factors responsible for the serious changes in the emotional and instinctive life which characterize these disorders must be sought for elsewhere than in the central nervous system, and it would seem probable that the source of these changes is to be found in the depths of the organic life—in disorders of the endocrine glands and the vegetative nervous system.

### INCOME TAX: THE THREE YEARS' AVERAGE.

THE Royal Commission on the Income Tax, which reported in March, 1920, received a good deal of evidence as to the suitability of a three years' average as a basis of assessment for professional and commercial profits. The report was emphatic on the point. Paragraph 479 says: "There has been a surprising weight of evidence in favour of the profits of the previous year being taken as the basis for Schedule D assessments. Hardly anyone has a good word to say for the average. . . . We have therefore no hesitation in recommending that the change be made." The change has been some time in coming, but that is perhaps not unnatural. In such a matter the interests of the Exchequer and the taxpayer are directly opposed. No Chancellor could very well desire the change if it meant that two "good" years would drop out of the average, while taxpayers as a whole would have a real grievance if the change were introduced at a moment which would enable the Chancellor

to collect tax on a single year's basis appreciably in excess of the amount payable on the basis which was discarded in their general interest.

Presumably when he was laying his plans for the 1926-27 Budget Mr. Churchill felt that he could reasonably expect the profits of 1926 to be fairly normal, and therefore to provide a suitable starting-point for the new basis. Accordingly there has been inserted in the Finance Act a group of sections, Part IV of the Act, the effect of which is, broadly, to sweep away the three years' average and to substitute the basis of the previous year. Having regard to the general expectation that profits are being adversely affected by the coal strike, it is perhaps unsafe to assume that second thoughts will not lead to the change being still further postponed. It is, of course, obvious that such a change, even if effected in a year when the profits of the nation were normal, might work unfairly as between one taxpayer and another, and it has therefore always been assumed that the change would be accompanied by some special relaxations to mitigate individual hardship. Some of the modifications introduced have reference to professions "set up" or "permanently discontinued"; a medical practice falling under either of these heads would not normally be yielding substantial profits, and consequently those sections are not of direct interest to practitioners. It may, however, be remarked in passing that the new rule which requires that the final year of a discontinued business or practice shall be assessed at the amount of the profit for that year will prevent a certain amount of "legitimate evasion" to which the three years' average is said to have lent itself in some branches of commerce.

The new rule which is of importance to medical practitioners is Section 29, Subsection 3, of the Finance Act, 1926. Where the change involves individual hardship it will presumably be because the years 1924 and/or 1925 were comparatively poor, so that their exclusion from the calculation of the 1927-28 assessment will adversely affect the practitioner. The line taken is that cases of substantial hardship will be met, but not those where the adverse effect is comparatively small; and the means for giving this partial relief are rather ingenious. It is important that our readers should appreciate the position, and we therefore make no apology for stating it in some detail. The relief given consists in affording the taxpayer the option, in certain circumstances, of having his assessments for 1927-28 and 1928-29 (the option applies to the two years, but not to only one of them) made on the three years' average. This right of choice, which must be exercised not later than October 5th, 1927, arises where the profits of 1924 or 1925 are less than the average profits of the six years to 1923 inclusive. It follows, therefore, that a practitioner will be well advised to examine his past returns before the time limit expires, to see whether he has this option, and if so to decide whether it is in his interest to exercise it. In making the latter decision he should have regard to his probable earnings for 1927; if they are likely to be small it may suit him best to allow his option to expire unexercised. If the taxpayer has not been in possession of the source of profits during the whole of the specified six years, he can take for the purpose of the comparison the average over the period during which he has been in possession of that source. The proviso dealing with partnerships has peculiar relevance to the medical profession. It will be realized that alterations in the personnel of partnerships would, by destroying the continuity of possession of the source

of profit of the person (that is, the firm) assessed, in many cases render the option nugatory unless steps were taken to obviate it. That point is met by providing that persons in partnership shall be deemed to have been in possession of the source of profit during any year if any of them was in that year a whole or part proprietor. If, for instance, X, Y, and Z succeeded to a practice carried on by X and Q up to December 31st, 1923, their profits for 1924 or 1925 can be compared with the average profits of X and Q for the previous six years. It is not unlikely that practitioners will find that the existence of the option will depend in particular cases on the years in which there was abnormal expenditure—for example, incurred in the replacement of motor cars. Where such replacements have occurred in 1924 or 1925 that may very well bring the option into play, and in that way compensate the practitioner for the partial loss of the allowance which the abandonment of the three years' average would otherwise entail.

The change has long been overdue, and we congratulate Mr. Churchill on the preparations he has made to give effect to it next year, at the same time cherishing the hope that he will not allow himself to be affected by the depressing financial circumstances of 1926, and shrink from the plunge when the time comes for the final decision next April.

#### OPIUM POLICY IN INDIA.

REPORTS from Geneva indicate that there have been lively discussions in the fifth committee of the League of Nations over the opium question.<sup>1</sup> Disappointment was expressed, even by those who were mainly responsible for the Geneva Opium Convention of 1925, at the few ratifications of that convention which have been as yet deposited; while the Italian delegate hotly dissented from Viscount Cecil's remarks, and maintained that the convention of 1925 was, in fact, in some respects a step backwards from the Hague International Opium Convention of 1912. Except for the new opium policy of the Indian Government, whereby export of opium for other than medicinal purposes is to be reduced progressively and extinguished within a definite period, there would seem to be little advance to record during the past year. This policy has been endorsed by the Council of State and carried "amidst acclamations" by the Legislative Assembly of India; though a recent reply in the House of Commons has indicated that the period within which extinction of exports is to be achieved has been extended to ten years. A pamphlet recently published by the Foreign Policy Association of America gives a concise summary of "The Opium Situation in India."<sup>2</sup> It postulates the world's medical requirement of opium at 350 tons a year, whereas a minimum estimate of the world's total production of opium is put at 3,500 tons a year. The surplus is accounted for by its use for smoking in the Far East, for eating in India, and by illicit traffic. Four countries are the main producers of opium—namely, Turkey, Persia, India, and China. The opium of the two latter countries is mainly consumed either by smoking or eating; that from the two former countries is largely used for medicinal purposes, for the production of morphine and other alkaloids, although much finds its way into illicit hands, and is used for non-medicinal purposes. The results of the Geneva conferences of 1924-25 are thus summarized: "No agreement could be reached on reduction of production to medical needs. The ten-year period for suppression of opium smoking (proposed by the United States) was extended to fifteen years, and made contingent on control of smuggling

from China and other producing countries. The United States and China withdrew before the conferences ended, but the other countries completed and signed two treaties, one dealing with smoking opium, the other regulating control of drugs." The question is raised, but not answered, as to whence the countries which have hitherto derived their supplies of smoking opium from India will obtain the drug when India ceases to export, if they fail to suppress the smoking of opium. In 1923-24 India exported more than a million pounds of opium to the Straits Settlements, India, China, Siam, Persia, Dutch East Indies, North Borneo, and Japan. As regards eating opium in India, a use of the drug which the Government has held, on the doubtful authority of the Royal Commission of 1893-94, to be "legitimate" and salutary—a matter of merely domestic concern and not one for international investigation—new light has recently been thrown on the problem by various non-official investigations and by discussions in the Legislative Assembly. Accepting the League of Nations index figure as 12 lb. of opium per annum for 10,000 population to meet medical requirements, it appears that while the average for all India is stated to be 24 lb., in Assam it is 104 lb., in parts of the Punjab over 100 lb., in Bombay 85 lb., in Rangoon 218 lb., and in Calcutta 287 lb. Such variations in the distribution of consumption point to opium addiction in particular towns and districts, and cannot be explained by its use as a domestic remedy in places where medical advice is not available. The relatively low average of consumption for the whole of India masks the grave addiction in certain localities, and shows that in rural areas this "treasured household remedy" is not so widely resorted to as may have been supposed. It is well to know that this question of internal consumption of opium in India is engaging the attention both of the Government of India and the local governments in the different provinces.

#### HOSPITAL CONSTRUCTION.

IN view of the prevalence of schemes for the rebuilding or extension of voluntary hospitals, an eight-page memorandum<sup>1</sup> has been prepared by the Voluntary Hospital Commission to guide those concerned in planning buildings which shall combine economy of cost and administration with suitability for their special requirements and allow extension in the future. Hints are given about the site, nature of access, including road-making, general disposition of the buildings for convenient grouping of patients, simplifying the service, and how to obtain the maximum sunlight. Hospital buildings are now less solidly and elaborately built than was the case during last century, and the provision of verandahs, roof wards, and sliding windows to wards is becoming more general. Modern buildings are simple in character, inexpensive in treatment, and depend for their pleasing effects on good design, appropriate grouping, and correct proportions. Buildings may be classed as permanent, semi-permanent, and temporary, and it is indicated that an apparent economy in adopting the cheaper and less permanent types may prove to be fallacious, since the saving in cost is usually less than the reduction in value. Such an initial compromise as the provision of permanent and fireproof walls and floors, with a subdivision into rooms by the use of partitions and not of permanent walls, may be advisable in some cases. Detailed recommendations are given about the construction of floors, interior linings of the walls, sanitary fittings, heating, and windows. The pavilion form of ward arrangement is becoming increasingly popular, and good cross-ventilation is so obtainable. Pavilions of three stories require lifts, and it is considered inadvisable to exceed this height in this country. In America, on the other hand,

<sup>1</sup> Memorandum on the Construction of Voluntary Hospitals. Voluntary Hospital Commission 17. Published by H.M. Stationery Office. Price 2d. net.

<sup>2</sup> BRITISH MEDICAL JOURNAL, September 18th, 1926, p. 537.

<sup>3</sup> F.P.A. Pamphlet No. 39. Series of 1925-26. May, 1926. New York City.

it is becoming more and more the practice to erect lofty hospital buildings, thus securing concentration of service, plumbing, and heating. Two rows of eight to twelve beds each are most convenient for a general ward, and at least one small isolation ward should be available. Sanitary annexes with cross-ventilated entrances should be readily accessible, and in each ward a large fixed wash-basin for staff use, with hot and cold water laid on, saves much labour. It is recommended that in main wards for adults a wall space of 8 feet per bed should be allowed, a floor space of not less than 86 square feet, and a capacity of not less than 1,056 cubic feet. In open-air wards having a single row of beds the wall space should not be decreased, but reduction can be made in the floor and cubic space. In isolation wards for one bed only, 120 square feet of floor space and 1,200 cubic feet are advisable, and for more than one bed the standards suggested for main wards are applicable. In most hospitals the provision of some day-room accommodation for ambulant patients is desirable. The operation department should be central, with a northerly aspect, readily accessible, and with the radiological department near. The out-patient department should form a separate block connected by a covered corridor with the receiving and casualty department. Practical suggestions are given in this memorandum about the disposition of administrative accommodation; and in general it will be found to be a valuable summary of the main points concerned in modern hospital construction.

#### THE LEAGUE OF NATIONS AND THE UNIVERSITIES.

Nor all the delegates attending the present Assembly of the League of Nations come from the senates and embassies. Quite a number this year have come from seats of learning. Almost every university of Europe is represented at Geneva. The French delegation includes two professors—one from the University of Paris and the other from that of Lille. The Belgian delegation is headed by the professor of social science at Brussels. Norway has sent two professors; one of them, Dr. Fridtjof Nansen, G.C.V.O., the Arctic explorer, has been professor of oceanography at Oslo since 1908. Finland is represented by a professor from Helsinki, and Rumania by two professors—one from Buearest and the other from Cluz. One of the Swiss delegates has a university chair at Berne, and one of the Polish delegates is dean of the University of Cracow. All the five delegates and substitute delegates for the Netherlands are doctors of law and political science, and the most prominent of them is professor at Leyden. The Irish Free State has sent a professor from the National University of Ireland. The German delegates number about twenty-four persons, including the technical experts, and fifteen of them hold doctorates. Of the women delegates one of them is a Swedish master of law, and another a member of the Rumanian Academy. Only three medical men, apparently, are attending the Assembly in an official capacity. One of these is Sir George Buchanan, C.B., M.D., of the Ministry of Health, who is attached as an expert to the British delegation; another is the Hon. Philippe Roy, M.D., Commissioner-General for Canada in France; and the third is Dr. Domingo Ramos, who has taken a leading part in introducing into Cuba the principles of infant hygiene. The question of some international linkage of universities has been the subject of long discussions in the committees of the present Assembly. Italy, among other countries, is setting out to attract foreign students, by organizing special courses for them at the universities, with exemption from taxation during their stay, and with travelling facilities. Canada is establishing in the university centre of Paris a Canadian house for its students. The work of international interchange of professors and students is being subsidized by the Polish

and Czecho-Slovakian Governments and by an educational organization in Germany. Dame Edith Lyttelton, on behalf of Great Britain, assured the Assembly of the sympathy of her Government in any system of international scholarships and exchanges, and similar expressions were made by the delegates of Rumania and of the Netherlands. This work, so far as it has assumed any shape at all, is being done through the International Institute of Intellectual Co-operation, recently set up in Paris as the result of a gift to the League by the French Government.

#### TROPICAL TYPHUS.

DRS. WILLIAM FLETCHER and J. E. LESSLAR<sup>1</sup> of the Hospital for Medical Research, Kuala Lumpur, Federated Malay States, have given the name of "tropical typhus" to a disease which differs from ordinary typhus by its low infectivity, though the symptoms and behaviour of the Weil-Felix reaction are identical in both forms. The epidemiological features, however, are so fundamentally different in tropical typhus that they do not bear even a family resemblance to those of the epidemic disease. There is no evidence of the direct infection from man to man which occurs so readily in epidemic typhus. No body-lice were found on any of the patients, and there was strong evidence that these insects were not the vectors. On the other hand, the virus seems to be connected in some way with open, uncultivated grazing land. One of the most striking features of the disease as it exists in the Federated Malay States is its race incidence. Compared with the Malays, Chinese, and Tamils who form the bulk of the population, the numbers of other nations are comparatively insignificant. Punjabis constitute less than 1 per cent., and Europeans were less than 0.5 per cent.; yet seven of the typhus patients were Europeans and seven were Punjabis; only four were Tamils, and there were no Malays or Chinese. Nearly all the Asiatic patients were cowkeepers, and the high incidence of the disease among Punjabis is probably due to so many of them following this occupation. The number of Europeans affected is explained by the association of six of them with the same source of infection. The treatment of tropical typhus is the same as that of the epidemic form, but is easier to carry out because there is less likelihood of the infection spreading to the attendants. The authors maintain that the tropical typhus of the Malay States bears a close resemblance to the typhus-like disease described by other authors in different parts of Asia, Africa, and America, and in a recent communication<sup>2</sup> attribute the contradictory results of the Weil-Felix reaction to different strains being used in various countries.

#### DEGREES FOR PRACTITIONERS: M.D. LAUSANNE.

Or the five Cantonal or State universities in Switzerland which have a faculty of medicine and grant the degree of Doctor in Medicine, it is not as widely known as it might be that two of these—Lausanne and Berne—welcome British practitioners and allow them to proceed to the M.D. degree under reasonable conditions. The University of Lausanne has some thirty-five professors in the Faculty of Medicine, and about 800 students and 200 auditeurs attend the university. The teaching hospital, the Cantonal, situated in the Avenue du Buglon, contains some 500 beds, and the children's and maternity blocks on the other side of the road, built in 1916, contain a further 200 beds, surpassing in design, construction, and equipment any hospital in Europe. British practitioners are received upon the same footing as the Swiss holding the Swiss Federal Diploma, and may obtain the M.D. degree on complying with the following regulations. (1) Matriculation in the university and registration as a student, on production of

<sup>1</sup> *Bull. Inst. Med. Research, Federated Malay States, 1925, No. 2*

<sup>2</sup> *Ibid., 1926, No. 1*

a matriculation certificate of any British university, or of any preliminary examination recognized by the General Medical Council for the purposes of registration as a medical student; also production of the certificate of the degree or diploma qualifying for practice in the United Kingdom and the certificate of registration as a medical practitioner in the United Kingdom. (2) Undergoing with success a colloquium—that is, a viva voce examination—in any three of the subjects of the final medical examination, at the choice of the candidate—for example, medicine, surgery, diseases of children, or midwifery. (3) The presentation of a thesis for the doctorate, which has been prepared and completed in the clinic under the direction of one of the professors in the Faculty of Medicine, in any subject in the medical curriculum. Condition (1) is usually complied with upon arrival, (2) after about three months, and (3) at the end of the session. Most of the professors speak English well, and the choice of subject for the thesis may be made by the candidate and approved by the professor, or may be made by the professor himself. The standard, though high, is well within the reach of steady work during the required semester of residence (October to March). After the thesis has been accepted by the Faculty of Medicine its printing is authorized by the dean, and 200 copies have to be handed in—150 to the university and 50 to the dean. The fees are: On matriculation 20 francs; on inscription for the colloquium 50 francs; on presentation of thesis 200 francs; diploma and graduation 25 francs; courses, lectures, library, and laboratory fees about 80 francs; the printing of the thesis costs about £7 to £12, according to length, tables, diagrams, etc. It is possible to live comfortably for £10 a month. Applications for admission should be made to the Dean of the Faculty of Medicine, *École de Médecine*, Place de l'Ours, Lausanne, and to the professor in the subject in which the candidate wishes to do his thesis. The *Students' Guide* is issued in October and April, and may be obtained for 50 centimes from F. Haeshel-Dufey, 3, Rue Centrale, Lausanne (*Guide de l'Étudiant*). Further particulars may be obtained from C. A. H. Franklin, M.D., honorary secretary of the Lausanne Medical Graduates, 56, Southborough Road, Bickley, Kent. The winter session 1926-27 opens on October 13th. It should be made clear that the university degree of M.D. does not confer the right to practise in Switzerland, which requires the possession of the State or Federal Diploma, the examinations for which are conducted by a board of examiners drawn from all the universities. The Swiss students, after matriculating in one of the universities, pursue a five years' course of study, taking the first, second, and final examinations for the federal diploma; when this has been obtained, they proceed a year or so later to the M.D. degree of their own Alma Mater (though they may take it in any of their universities), the Federal Diploma thus corresponding to our own M.B. The Swiss do not make it easy for foreigners to practise in Switzerland, as the cheapness of higher education gives them more doctors than they require, but they welcome British practitioners for a period of study and to spend a time in one of their schools.

#### IN PRAISE OF GAS FIRES.

At the Smoke Abatement Exhibition at Birmingham on September 16th a paper on the "Contribution of the gas industry to the problem of smoke abatement" was read by Sir Arthur Duckham, Director-General of Aircraft Production, and an authority on the carbonization of coal. He said that the domestic fire was the chief producer of smoke, and was responsible for five-sixths of the total production. It appears that of the 180 million tons of coal consumed annually in this country in normal times, about 40 million tons are used for domestic purposes. While

from the average factory furnace only about 0.5 per cent. of the coal escaped in the form of soot, no less than 6 per cent. escapes in this form from the tops of domestic chimneys. When coal is carbonized the gaseous and solid fuels obtained are smokeless when burned. Moreover, a considerable amount of sulphur is eliminated from the products, and so does not pass into the atmosphere. Birmingham, according to Sir Arthur Duckham, has taken the lead in substituting gas for coal in its manufactories, and also in domestic heating and lighting, although in the latter respect it is almost equalled by some of the large health resorts. In Great Britain Birmingham comes first with a consumption of 285 therms of gas per consumer per annum. In Bournemouth and Bath the consumption is about 250 therms. In several new housing estates and garden cities the houses are being rendered non-smoke-producing by the installation of a gas cooker, a gas boiler, and two gas fires. The development of small efficient hot-water boilers, working on gas or coke, is overcoming any hot-water difficulty. Sir Arthur Duckham laid down the general rule that domestic cooking and heating should be done by gas, and the general heating of water by coke if a continuous supply is required. The gas industry is certainly doing its best to overcome the Englishman's liking for the companionship of a coal fire, by artistic improvement in gas stoves, and by a study of the ways in which gas coke can be cleaned and graded before delivery, and the consumer instructed in the proper way of burning it. An additional advantage is claimed for the independent water-heating apparatus, using gas or coke, in that radiators can easily be installed. In Sir Arthur Duckham's opinion the gas industry has placed remedies against smoke in the hands of consumers, and the production of smoke is a crime against our national welfare. While sympathizing in general with his views on smoke abatement, we are not quite sure he is correct, however, when he says that fear of "that family bugbear cold in the head or on the chest is greatly reduced" by central heating.

#### OPHTHALMIC WORK IN EGYPT.

THE tenth annual report on the ophthalmic work of Egypt<sup>1</sup> has just been issued. It is noted that a grant was made by the Imperial War Graves Commission, as a memorial to the men of the Egyptian Labour Corps and Camel Transport Corps who fell in the great war, for the building of a permanent laboratory at the hospital at Giza. The Egyptian Government has made a grant for the equipment of the laboratory. The most interesting section of the report is that dealing with blindness. The definition of blindness adopted is that proposed by Trousseau— inability to count fingers at one metre. Of the causes of blindness the results of conjunctivitis are the most important, as they account for nearly two-thirds of all the cases; glaucoma and cataract are responsible for some 5 per cent. each; the number of other cases—due, for example, to congenital defect, accidents, and uveal disease—is relatively small. A census of the blind taken in 1917 showed a small decrease as compared with those enumerated ten years earlier. It is stated that 31 per 1,000 of the population were blind in one eye and 12 in both. Moslems account for 44 per cent., Christians 37, and Jews 20. At all ages the percentage of males suffering from total blindness is greater than that of females. The figures obtained for infants under 1 year are thought to be relatively valueless. The greatest increase is between 1 and 9 years, when the proportion is practically doubled. The number of cases of total blindness increases to a striking extent after 40 years of age. School medical inspection and the treatment of elementary school children have led to a very real advance in dealing with trachoma.

## CANCER OF THE BREAST.

## THE MINISTRY OF HEALTH MEMORANDUM.

THE new memorandum (Circular 716<sup>1</sup>) of the Ministry of Health on cancer of the breast, to the issue of which we called attention last week, is an extended and revised version of Circular 496, which was published in May, 1924. In this revision additional and more exact data, based chiefly on investigations by Dr. Janet Lane-Claypon, by a subcommittee consisting of medical officers of health of several great cities, and at Leeds, have been incorporated. The time has been thought ripe also for a section on the practical applications of the information which has been accumulated so far by the Departmental Committee on Cancer, of which Sir George Newman is chairman.

In the introduction to the memorandum it is pointed out that no other organ contributes more largely than the breast to the cancer mortality amongst women in England and Wales; that the upper and outer quarter of the organ is the situation in which cancer most commonly appears, and that the area surrounding the nipple is the next most common seat of the disease. The memorandum then describes the natural course of mammary cancer, and calls attention to the facts that the onset cannot be fixed with any degree of accuracy; that even in women of the same age and the same habit of body some cases run an acute and others a chronic course; and that age appears to have some influence on the course of the disease. The average natural duration of a case of cancer of the breast seems to be a little over three years.

*Etiology and Diagnosis.*

The Departmental Committee has come to the conclusion that recent investigations have demonstrated statistically that chronic mastitis and a history of injury are more commonly found in women who develop cancer than in those who remain unaffected. The investigations have shown also that the less fertile married women, those who have had acute transient mastitis, deformity or abnormality of the breast, and possibly those in whom suckling has been absent or excessively prolonged, are more liable to suffer from the disease. Neither disturbances of menstruation and the menopause nor the nature of confinements can be shown to exert any influence. The committee thinks this knowledge may open up a wide field of investigation for tracing the development of cancer back to its starting point.

Under the heading diagnosis, stress is naturally laid upon the early identification of the nature of a mass in the breast. The committee dismisses as dangerous and inconvenient the method of removing a portion of the growth for microscopical examination. It finds that the method of examining microscopical sections during the course of an operation has proved unsatisfactory, since masses which are difficult to identify with the naked eye are very frequently those which display doubtful appearances under the rapid microscopical examination during operation. The greatest reliability and least risk is to be found in incising the growth at the time of operation and being guided as to subsequent procedure by the naked-eye appearance of the incised tumour, every care being taken to avoid transference of cancer cells to the wound.

*Operative Treatment.*

At the present time the one chance for a patient with cancer of the breast is early surgical operation. The memorandum discusses operation from the standpoint of the surgeon and from the standpoint of the patient. It is the point of view of the patient which, in the opinion of the committee, has led to the unfortunate position that with improvement in surgical technique there has been no corresponding increase in the proportion of cases which reach the surgeon at a stage when operation offers the greatest advantage. On the average, patients do not seek medical advice until eight or ten months after the growth was first noticed, and it is hinted that even by the medical profession the good results achieved by early operation are imperfectly appreciated.

<sup>1</sup> H.M. Stationery Office, Id. net

What is the measure of the success of surgical treatment? The memorandum sets forth the results of the special investigation carried out at Leeds, and contained in the Ministry of Health 1926 reports on public health and medical subjects No. 34.<sup>2</sup> This investigation showed that, with the modern complete operation, 52 per cent. of all the patients were alive and well after three years, 39 per cent. after five years, and 30 per cent. after ten years. But if the patients were classed as being in the early, middle, and late stages of the disease when operated on, it was found that of the early cases 94 per cent. were alive and well after three years, 91 per cent. after five years, and 87 per cent. at the end of ten years. The committee summarizes the position thus:

"On the average women affected by cancer of the breast have, in the absence of effective treatment, roughly one-sixth of the normal duration of life to look forward to; those subjected to the complete operation during the comparatively early stage of the disease at which the average patient applies for treatment under present unsatisfactory conditions have about one-third of the normal duration to expect; while those so operated upon at an early stage may anticipate approximately two-thirds of the normal after life-time."

It is estimated by the committee that about 50 per cent. of the total number of sufferers from mammary cancer undergo operation in large hospitals. Of the others some are operated on at their own homes, in nursing homes, and in cottage hospitals, others attend hospital too late for operation, while the remainder probably fall into the hands of unqualified practitioners or come under the care of registered medical men only at the latest stage. Not more than one in five or six of all victims of the disease obtains the best treatment available.

*Measures to Reduce Mortality.*

To reduce mortality every possible means should be taken to induce all women who are conscious of any abnormal condition in the breast to seek medical advice without delay, especially if they have reached, or are reaching, middle age. The committee suggests that for this purpose the information set out in the memorandum should be disseminated by leaflets, "talks," advice by local cancer committees, doctors, health visitors, and social workers. Educative advice, it is thought, should be of value, if directed towards securing treatment of the earlier conditions which precede cancer, and towards the avoidance of injury, especially habitual injury. The committee thinks that the intensive researches now being carried out may lead to the discovery of the cause of malignant disease, and yet may not necessarily indicate a means of prevention; also that preventive measures could not secure early results, since the disease is one of slow development due to effective or predisposing causes operating over a prolonged period. Hence the necessity of all the educative and remedial measures now available.

*The Situation Generally.*

In a memorandum such as that before us, addressed in as non-technical language as possible to local authorities consisting of laymen, there is, of course, little that is controversial. It is gratifying to learn that the departmental committee has satisfied itself statistically that the results of so-called early operation are so good. It is clear that no operation can be really early, since the growth of cancerous cells must have proceeded a long way before any mass in the breast becomes appreciable to the touch. It is italicized in the memorandum that "in its early stages cancer is usually unattended by pain," so that it is by palpation of a mass alone that early diagnosis can be made. Hence the disappointment which sometimes occurs when recurrence follows a complete operation for a growth which is no bigger than a pea. The educative advice proposed by the departmental committee for the purpose of securing treatment of conditions preceding cancer, and for the avoidance of injury, is based, no doubt, on Dr. Janet Lane-Claypon's report on "associated antecedent conditions," upon which we commented on March 6th last (p. 437). We still feel the doubt we then expressed whether the statistical method is conclusive on the close association between injury and the subsequent development of cancer. The human factor is too uncertain. We still maintain that a person

<sup>2</sup> BRITISH MEDICAL JOURNAL, August 14th, 1926, p. 318.

who develops cancer in an organ so liable to injury as the breast is much more likely to dig out from the "sub-conscious memory" instances of injury than one who is not suffering from cancer.

Of the advantages of early operation for mammary cancer there can be no doubt; it is equally certain that there is a tendency in the human being to postpone action which is unpleasant. Any reasonable proposal for overcoming this prejudice is justifiable; and to this extent another disease campaign is justified. We hope, however, that the female population will steer a middle course between the extremes of daily anxious breast palpation and devil-may-care insouciance. We hope, too, that the leaflets and "talks" of local cancer committees will not be made too lurid. The results of campaigns are rarely commensurate with the time, money, and energy expended on them; but measured and reasoned statements of the case, such as are given in the memorandum of the Ministry of Health, have an educative value which, though gradual, has in the end more permanent effect than mere luridity.

## INDUSTRIAL FATIGUE.

### WORK OF THE RESEARCH BOARD.

THE sixth annual report<sup>1</sup> of the Industrial Fatigue Research Board to December 31st, 1925, includes an analysis of the published work of the Board since its formation in 1918. For this reason, as well as on account of the interest of the report, it may be well to attempt something more than a mere summary of the purely medical aspects of the work of the Board. The machinery for the work consists of two kinds of committees—one, homogeneous from a scientific point of view, dealing with statistics, physiology of muscular work, and industrial psychology; the other kind heterogeneous, in that the committees are constituted of experts in the appropriate sciences, industrial representatives, and medical or technical experts. The work of the Board is roughly divided into three categories: (a) investigations of particular problems of wide industrial importance; (b) studies of specific problems submitted by Government departments or industrial associations; (c) experimental researches in university and other laboratories.

### Definition of Industrial Fatigue.

The report calls attention to criticism which has been directed against the term "industrial fatigue." It is said to be used to cover widely different phenomena, ranging from physiological muscular fatigue to boredom or ennui. It is also stated that the causes underlying fatigue are so varied and complex that any precise definition of the word is at present impossible. The report defends the use of the term if it be accepted quite loosely to include not merely the lessened capacity or inclination which results from previous doing of the same kind of work, but also all conditions affecting the body or mind that impede the normal man from working at his maximum efficiency. It will be seen, therefore, that the scope for its operations set by the Board is very wide, and might be made to comprise the effects of numerous sociological and economic factors. It has limited its functions, however, to conditions concerned with the factory itself, and hitherto has dealt very little with external factors, even when, like housing and transport, they have a direct bearing on efficiency in the factory.

The forty-three reports already issued by the Board, together with some twenty-four other articles or reports mainly by workers for the Board, have been collated and combined into three groups according to whether their principal points relate to the effects on fatigue and efficiency of (a) hours of labour, including spells, shifts, and rest pauses; (b) conditions of employment, such as ventilation and lighting; (c) methods of work, constituting the personal factors in efficiency and fatigue, such as vocational psychology and movement study.

For the estimation of industrial fatigue attempts have been made to employ two kinds of test—direct and indirect. The first consists in the application to the person himself of some previously standardized test. So far the problem

of evolving a direct and immediate test has eluded solution, and the Board has had to rely on indirect tests—namely, variations in output and other tests of performance, sickness and mortality, labour turnover (which means the rate of change in the working staff), lost time, and accidents.

### Hours and Output.

Under the heading "hours of labour" the report sets forth the variations in output that occur during the day, during the week, and over longer periods. Thus in the daily work there is often a "saddle-back" curve, an initial rise of output attributable to incitement, and a final drop attributable to fatigue. With mental or light work, however, the curve is often different, showing a fall in output during each spell, owing to monotony, with a final spurt in the afternoon at the approach of the end of work for the day. The weekly curves show that output is nearly always low on Monday and at the end of the week, and that the increased efficiency due to practice, which causes a rise in output, is neutralized by fatigue effects towards the end of the week. It is noted, however, that the distribution of output may be affected by some special incentive such as pay day. In longer periods there is a marked spurt observable in the second week before the annual holidays begin. Output is also affected by the length of shift; a reduction in the length of shift has often been followed by an increase in output per hour, though we gather that the percentage hourly increase with a shorter shift does not always lead to the production of the same total output obtainable with the longer shift. The false economy of hours of work above a certain length demonstrated by the Health of Munition Workers' Committee during the war is perhaps liable to misuse as an argument in times of peace.

A good deal of work has been done for the Board on the subject of "rest pauses," and the observers have satisfied themselves that the introduction of rest pauses brings about an unconscious increase in output. The slowest workers generally benefit most from the system. Improvement in output may also occur with changes of activity, but the results are at present inconclusive, though suggesting that there may be an optimum condition between extreme uniformity and frequent change.

### Conditions of Work.

As regards conditions of employment, the Board has made investigations into temperature, humidity, ventilation, and lighting, but has not, so far, dealt with noise, vibration, and dust. In some processes the workers' environment is independent of the conditions of manufacture; in others the environment is unfavourably affected by conditions which are not essential to the process, so that the investigator can freely suggest improvement. But there is a third class of process, such as some forms of weaving, where an unfavourable environment is required for manufacturing processes, and all that can be done is to bring about some degree of physiological improvement.

Observations made by investigators show that in heavy work involving exposure to high temperature the output is greatest in winter and least in summer. The adverse effect of higher temperatures and humidities on working capacity is shown by the longer time unconsciously taken by weavers to deal with stoppage and breakage when temperature and humidity reach a certain level. Ventilation has been closely studied by Dr. Vernon and others; the cooling power of air and air movement being measured by the kathermometer. It is physiologically desirable that the head should be at a lower temperature than the feet, and that the temperature gradient between floor and head level should be as slight as possible. This is best achieved by placing the means of heating low or beneath the floor, instead of using steam-pipes above the head. It has been found that artificial lighting causes a fall in output, especially great in textile industries.

### Vocational Psychology.

The study of the effect of methods of work brings us to the subject of vocational psychology. At present the initial selection of an occupation is often a matter of chance, and permanent employment is only secured after a process of trial and error. Consequently the "labour turnover"

<sup>1</sup> 1926. H.M. Stationery Office. 3s. net.

amongst beginners is high. This has led to the development of vocational selection and guidance. In collaboration with the National Institute of Industrial Psychology the Board carried out an investigation of the occupations taken up by 2,000 children leaving schools in a London borough. An intensive individual study of all the children due to leave three of the schools in the following twelve months was then conducted, and vocational recommendations based on this study were made. After two years as many as possible of these children were traced. The complete study of the children involved examination of the home conditions, the physical conditions, and the mental conditions, including intelligence, specific capacities, educational attainments, special interests, emotional, moral, and social qualities. A distinct relationship was found between material prosperity of the homes and general intelligence of mothers and children; but the relationship was comparatively slight, the average intelligence of children from superior homes being only 20 per cent. above that of children from the poorest. Native intelligence, at any rate in children of school-leaving age, is regarded as of outstanding importance in the choice of a career; and this is the easiest of all psychological characteristics to test reliably. It appears that judgement on well defined elementary traits, especially the emotional, is generally far more accurate than judgement on more complex moral qualities, such as honesty, industry, and reliability. Judgement on the latter is extremely fallible; and it is in this direction that more carefully developed tests are expected to prove valuable.

The results of the investigation into the success of vocational guidance are indefinite owing to the smallness of the numbers of children dealt with. Apparently about 84 per cent. of those traced are satisfied; 14 per cent. are satisfied with their work, but not with their pay or prospects; and only about 2 per cent. are dissatisfied with the work into which they were guided. Of those who went into work dissimilar to that recommended, 40 per cent. are satisfied, 18 per cent. satisfied with the work, but not with the pay and prospects, and 43 per cent. are dissatisfied.

The section in the report on movement and time study shows, first, that movement study is a logical sequel to vocational guidance and selection. It aims at providing standard methods of training for beginners. Several interesting accounts are given of the alteration in comfort and output achieved by teaching the workers more suitable movements in carrying on their work. Thus in outside grease dollying, a process applied in the manufacture of spoons and forks, the reduction in time effected by a standard method over an original method amounted to between 30 and 60 per cent.

#### *Some Reflections.*

The subject of industrial fatigue and the researches which are being carried out by the Board can be looked at from various points of view. Scientifically increase in knowledge of the human being, of his psychology and his reactions to industrial life, is of value, and should be of value to medical men, every one of whom is bound to meet patients on whom their employment has had some effect physically or mentally. For the employer of labour the researches are important, in that they may assist in increasing production, in lowering cost, in showing him how to get the maximum of efficiency from that physiological machine which is his worker. To the industrial worker himself the researches should bring greater comfort and less fatigue. To the philosopher it may perhaps occur to wonder what exactly will be the end of these researches. He may feel, in reading the report, a sort of vertigo at the thought of the time when every possible emotion, volition, and action of the worker has been analysed, sorted out, and provided for; until the "factory hand" has become a perfect robot-like machine, doing with the maximum of efficiency the maximum of work in the shortest possible time. But if the philosopher is also a man of science he will remember that all knowledge is of value, and that the investigators of the Industrial Fatigue Research Board have still left the whole of the worker's unemployed time, his home life, his loves, his hates, and his amusements, for subsequent research.

## OUT-RELIEF FOR SINGLE MINERS.

### THE SITUATION AT HOUGHTON-LE-SPRING.

THE following note describes briefly the trouble that has arisen in a coal-mining district through an attempt by the local board of guardians (the majority of whose members are professed socialists) to induce the medical officers to rescue it from a dilemma at the cost of their professional honour.

On August 16th and 17th the five part-time medical officers of the Houghton-le-Spring Union in the county of Durham had interviews with the board of guardians. The guardians informed them that outdoor relief had been given to single men since the beginning of the coal strike, the number being over 2,000. A letter had been received from the Ministry of Health pointing out that such indiscriminate relief was illegal; relief could only be given to single men if they were found on medical examination to be physically incapable of work by reason of want or privation. The guardians asked the doctors to get them out of this difficulty by giving such certificates to these men, certifying them to be incapable of work. The doctors were faced with the situation that to their knowledge the very large proportion of these 2,000 men were not so incapable, and the task of refusing certificates to such a large number of men who had been getting relief would carry serious consequences to themselves, their practices, and their property. They felt there was no alternative between incurring the odium of stopping this relief, or bowing before the pressure of local opinion and granting such certificates wholesale. One of the doctors was notified that 200 men would be at his house that evening, and 200 more on the following morning, for certificates.

After consultation with the British Medical Association the five medical officers decided that the only honourable course was to give a month's notice to resign their posts. They did so on August 17th, and in the joint letter of resignation stated that they would carry on their ordinary duties of attending to the sick poor during the month, but refused to carry out the duty of examining single men as to physical incapacity for work due to want and privation. The resignations were accepted on August 19th by the guardians, who advertised in the local papers for a whole-time medical man to do the work of the entire union, including the examinations in dispute, and asking candidates to state the salary required, applications to be received by August 26th.

During the interval representations were made to the doctors that the work might be made lighter by appointing all the doctors in practice in the area as temporary medical officers to assist the ordinary medical officers, no doctor examining a man who was his own patient; also that the relieving officer would not send such large numbers of men for examination, but only those about whom they had reasonable doubts. The whole of the doctors readily consented to participate in such an arrangement, and a scheme on these lines was drafted, which in the opinion of the doctors would enable them to examine these men and give certificates without fear or favour, and at the same time let each man feel that he had a fair examination. A letter was sent to the guardians on August 23rd stating that a deputation would wait on the guardians at 3 p.m. at its meeting on August 26th to lay the scheme before them. The deputation attended, but the guardians refused to see them.

No applications having been received for the whole-time medical officership, the guardians decided to advertise again and hold another meeting on September 2nd. In the meantime the guardians asked the medical officers to submit their scheme in writing. This was done by the honorary secretary of the Sunderland Division of the British Medical Association, Dr. R. H. Dix, whose handling of a very difficult and disagreeable situation has been beyond praise. No applications for the whole-time post were received, and the guardians asked the deputation to attend a meeting held on September 6th and discuss the scheme. The deputation (consisting of Dr. Dix, with a representative of the five medical officers, and a representative of the other local practitioners) attended the meeting, and on September 8th

the guardians agreed to work the scheme and rescinded the resolution accepting the resignations of the medical officers.

On September 10th medical examination boards were held in four of the five centres of the Houghton union. At Hetton the upper room of the Miners' Hall, where two medical men were examining applicants, was invaded by the assembled mob. The doctors on leaving the hall were followed down the street by 200 or 300 young men, some of whom struck them and threw stones. Both were hit by stones and only got away by motor omnibus after much rough handling. At the Herrington Centre the medical examinations were interrupted by members of the board of guardians, who abused the doctors and made speeches to the crowd outside. At the Houghton Centre there was a jeering and hooting mob, which eventually numbered about 600; police protection had to be sought, and the doctors escaped by making their way through the workhouse and down a side street.

In view of these hostile demonstrations the doctors have, very naturally, refused to go on with the examinations. They are carrying out their ordinary duties as parish medical officers, but no solution of the difficulty has yet been evolved.

## India.

### MEDICAL AID FOR WOMEN IN INDIA.

Four annual reports for 1925 of organizations of which Lady Reading was president until her departure from India have been published in one volume, and give a valuable survey of the work in preventing and treating disease in women in India that is being carried on by women. The four organizations are the National Association for Supplying Medical Aid by Women to the Women of India, which incorporates the Countess of Dufferin's Fund and the Women's Medical Service; the Victoria Memorial Scholarships Fund; the Lady Chelmsford All-India League for Maternity and Child Welfare; and the Lady Reading Women of India Fund, of which this is the final report. Grants from the Countess of Dufferin's Fund have been made to hospitals in the provinces where Women's Medical Service doctors are employed, as these institutions are still very poorly supported locally. In medical colleges and schools 256 students are working, of whom 108 are in the Lady Hardinge Medical College at Delhi. The hospital in connexion with this college provides clinical material in its 200 beds for the instruction of the women medical students in the last three years of their M.B., B.S. course, and it supplies medical aid by women for the women and children of the rapidly growing population of the new capital of Delhi and its surroundings. The students come from fourteen different provinces and States, and in the session 1924-25 thirteen graduated, as compared with eight in the previous year. Dufferin Fund scholarships and stipends are held by twenty-six students in medical colleges at Delhi, Madras, Bombay, and Calcutta, who after graduation are employed when possible as house-surgeons or house-physicians in hospitals staffed by medical women. The Fund aids hospitals for women and children by supplying one or more Women's Medical Service officers to the hospital free of charge, and by giving grants. The hospitals so supplied have during last year treated over 30,000 in-patients, and more than 380,000 out-patients; some 7,000 maternity cases were attended and 24,231 operations were performed. The work of the Victoria Memorial Scholarships Fund has been limited mainly to the training of local native midwives by health visitors, who, on passing out of various health centres, are encouraged to establish classes for midwives as one of their first activities in a new area. The propaganda work formerly undertaken by the Fund is now entrusted to the Lady Chelmsford League, the Fund contributing financially to its support. In addition to travelling health exhibitions, magic lantern lectures on child welfare, flies, tuberculosis, small-pox, and other medical subjects are given in large towns and villages; baby weeks are held, and a considerable amount of training of midwives has been carried on. The Lady Chelmsford

League by concentrating on such propaganda and assisting the education of health visitors is benefiting the whole of India. The League assists four schools at Delhi, Madras, Punjab, and Calcutta, the first of these being entirely supported. Lady Reading contributed generously towards the provision of a new Delhi health school, and support has been received from private sources. The new school includes classrooms, a laboratory, a lecture hall and library, ample accommodation for a resident superintendent, and living quarters for twelve students. The infant welfare centre will be a model of its kind, and will serve a crowded area. The Lady Reading Women of India Fund has now been closed, its various objectives having been attained. The nurses' hostel at the Lady Hardinge College is occupied, and the Lady Reading Hospital at Simla, which has been actively at work since 1924, has been endowed financially for the future.

### PUBLIC HEALTH IN CALCUTTA.

In his annual report on the public health of Calcutta for 1924 Dr. H. M. Crake reports that the death rate for the town was slightly higher than in the previous year, thus indicating a check in the steady improvement which had been registered year by year since 1919. Only thirty-three cases of plague occurred—less than half the number in 1923. The very mild recrudescence of this disease in Calcutta is held to indicate the possibility of the complete disappearance of plague in the near future, though as recently as 1922 the mortality rose to 144—a reminder that conditions favourable to its spread still exist in the town. Although the cholera mortality rose slightly in the year under review the epidemic was comparatively mild. In Calcutta epidemics tend to recur at intervals of about ten years; in Bengal, as a whole, though there is evidence of cyclical periodicity, there is considerable variation, epidemics occurring in some cases at intervals of three years, in others of six, and in others of ten; similar variations have been observed in Madras. Two encouraging features in the case of Calcutta are the increasing length of time between severe epidemics and the persistence of a low level of cholera mortality, instead of a sharp rise following a decline, as has been the case in previous years. A marked increase in the mortality from malaria and tuberculosis was recorded, the greater prevalence of the former disease being particularly evident in two districts. Mohammedans suffered nearly four times as severely as Hindus, and it is suggested that this may be due to increased susceptibility, particularly in the case of young girls. The tuberculosis death rate rose, particularly in the urban parts of the town, almost the whole of the mortality being due to pulmonary disease; only 125 deaths resulted from other forms of tuberculosis, which may possibly be associated with the rarity of bovine tuberculosis in Bengal. Dr. Crake considers that the absence of the bovine infection accounts in part for the prevalence of a very acute type of disease in man, while the serious spread in Calcutta is attributed to the prevalence of promiscuous spitting. A higher mortality occurs among Indian Christians as compared with Mohammedans and Hindus, and this is especially noticeable in the case of girls over the age of 10, below which there is no evidence of increased susceptibility among females. Dr. Crake blames the retention of the purdah system in the densely populated gullies of the congested town for this heavy mortality among young girls, and also mentions in this connexion the frequency of early marriage, subjecting them to the strain of repeated pregnancies and prolonged periods of lactation. An antituberculosis scheme, including the appointment of a tuberculosis officer with eight assistant medical officers, for systematic house-to-house visiting, a dispensary, and a publicity bureau, has been approved by the Health Committee of the Municipal Council. During 1924 nine ward health associations were established to deal with cases of tuberculosis, malaria, and kala-azar; several dispensaries are open for treatment, and sanitary surveys are made. This work has developed particularly rapidly in the case of kala-azar; the more difficult sanitary and preventive work is progressing less rapidly. No severe epidemic of small-pox occurred in 1924, though in the later months of the year scattered and sporadic cases occurred regularly, and led up to the serious epidemic of 1925. Measles appeared in

epidemic form, and resulted in the worst outbreak since 1913, Hindu children appearing to be three times as susceptible to it as Mohammedans. There are now five maternity centres at work, with resident medical women, qualified midwives, and health visitors. Each centre is on the telephone, so that complicated cases can be transferred to hospital at any hour of the day or night. The Buldeodas Maternity Home was opened in the northern end of the town in March, 1924, and contains a maternity ward with twenty-two beds, a series of seven cubicles, and a well equipped room for labour; a septic ward and a septic labour room are also available. From March 1st to the end of the year 417 patients were admitted, 353 cases of labour were dealt with, of which 116 were abnormal; four patients died—two from eclampsia, one from septicaemia after very irregular treatment for five days outside the hospital, and one from heart disease. It is hoped to add an ante-natal and a post-natal clinic to the home. A new ambulance station was opened in Calcutta in July, 1924, and provides accommodation for ten cars, six of these being available for accident and non-infectious, and four for infectious, cases. During the year over 10,000 calls were received, and four new ambulances are to be provided in order to cope with the heavy demand.

## England and Wales.

### HOSPITAL ACCOMMODATION AT HARROGATE.

H.R.H. PRINCESS MARY VISCOUNTESS LASCELLES visited Harrogate on September 3rd to lay the foundation stone of the new infirmary. The existing infirmary was opened in 1883 by the grandfather of Viscount Lascelles, and in 1906 an extension was opened by Lady Harewood. Only fifty-four beds are at present available, and the senior surgeon to the infirmary, Mr. H. Frankling, called attention to the fact that in Harrogate there was only one hospital bed for every 721 residents. The waiting list was consequently very long. The new infirmary would be built and administered as economically as possible. The necessitous poor would have priority of treatment, but many persons were both willing and able to make some contribution towards their maintenance while in hospital. In the new contributory scheme which had only been in operation for six months there were already 5,000 members paying three-pence a week, which represented an annual income of £3,000 in normal years. To this must be added a grant from the employers of 25 per cent. of the workmen's contributions. Provision would be made as soon as possible for patients unable to pay the usual nursing home fees, but desiring to support the infirmary by paying for their own maintenance. Sir Berkeley Moynihan spoke warmly in favour of the establishment of wards and beds for paying patients. The provision of hospitals to-day was only a temporary measure, and very considerable additions would be required in the future.

### ROYAL INSTITUTE OF PUBLIC HEALTH.

Under the auspices of the Royal Institute of Public Health a series of lectures on problems of personal public health will be delivered at 37, Russell Square, on Wednesday afternoons at 4 p.m., from October 13th to December 8th inclusive. Sir William Willcox will open the course, and will speak on intestinal infections in relation to personal health and disease. The subjects of the three succeeding lectures are the prevention and treatment of eczematous conditions of the skin of occupational origin, by Dr. W. J. O'Donovan; town planning in relation to health, by Professor L. P. Abercrombie of Liverpool; and ventilation in relation to health, by Dr. H. M. Vernon, investigator for the National Fatigue Research Board. Professor Winifred Cullis will describe the application of industrial psychology to the home, and Dr. Reginald Miller will lecture on the problem of rheumatism and rheumatic heart disease in children. Dr. C. W. Saleeby will give a lecture entitled "From heliotherapy to heliohygiene," and Dr. P. C. Varrier-Jones will give an address on settlements for tuberculous workers. The series will be concluded by Dr. F. E. Fremantle, M.P., who will speak on the role of

Parliament in regard to health legislation. The Harben Lectures of the Institute will be delivered on the afternoons of November 15th, 18th, and 22nd by Professor W. W. C. Topley, on the subject of quantitative experiments in the study of infection and resistance. These lectures are open to all interested in medico-sociological problems. It is announced that the annual congress of the Institute in 1927 will be held at Ghent from June 1st to 7th.

## Correspondence.

### GOITRE IN CHILDHOOD.

SIR,—In your issue of September 11th I noticed correspondence on the above question. I do not think there is any doubt, as Dr. Turton states, that goitre is diminishing, at least the large colloid type of goitre. The whole question, however, of the causation of goitre is a difficult one. The theory put forward by Dr. Turton, that excess of lime has something to do with goitre prevalence, may be correct, and Sir James Berry (*BRITISH MEDICAL JOURNAL* of December 5th, 1925, p. 1060) has supported this view; on the other hand, there is a large amount of evidence which supports the opinion that alimentary infection either through polluted water or food is one of the causes; both causes might act together, and chalky supplies are very liable to pollution.

One of the places which I gave in my paper<sup>1</sup> as almost free from goitre was Margate, yet here the water comes from chalky strata and has a total hardness of 18, and a permanent hardness of 3.4, with chlorine as chloride 1.6. This water is also bacteriologically clean (see result of analysis by Mr. Hawkins and Dr. A. G. R. Foulerton contained in Dr. McCoombe's report on the health of Margate for 1925).

At Ramsgate Dr. Bannister tells me that enlargement of the thyroid was not observed in any child of 12 years of age during the survey in the schools in 1924, and that enlargement of the thyroid is a rare condition in the borough. He gives me the following extract from the analysis of the Ramsgate water supply: total hardness 33.3 parts, permanent hardness 10.9 parts, chlorine as salt 24.5 parts per 100,000.

At Bath Dr. Blackett states in his annual report for 1925 that the hardness of the water is 21 grains per gallon, and chlorine as chlorides 1 grain per gallon. The percentage of goitre in girls of 12 in the survey was 7.3, and boys of 12, 2.2 (annual report, school medical officer, Bath, 1924).

In my own district, where the water has a hardness of about 3 parts per 100,000, 4.2 per cent. boys of 12 had enlargement of the thyroid, and 17.5 girls of 12. I myself have carried out investigations at Bath and found that goitre was much less prevalent there than in my own district.

I only give the above details to show that any theory of goitre is difficult to prove and the excess of lime theory is no exception. It may be that there is a relationship between thyroid enlargement and calcium metabolism, but why should the chalky water supply in Kent not produce goitre and the chalky water supplies in Derbyshire produce it, or water like Bath with a lot of lime salts cause less goitre than the soft water supply of Glossop?

I entirely agree with Dr. Turton and Dr. Johnson that it is important to find out what happens after school life. I do not go so far as to say details of school life are valueless. I consider them very important, particularly if the children are carefully examined, but I do think they must be read with figures taken from examinations made after leaving school. This is one of the points I made in my paper and during the discussion at Nottingham. It is important also that any investigation after school should be made in co-operation with the school medical officer so as to prevent errors in diagnosis.

I do not think that there can be any doubt that goitre in children is to a certain extent physiological, but it is possible that the physiological enlargement may favour the onset of either endemic goitre or Graves's disease later

<sup>1</sup> *BRITISH MEDICAL JOURNAL*, August 23rd, 1926, p. 571.

in life. In conclusion I must say—and I think Dr. Turton and Dr. Johnson will agree—that the whole question is one for further inquiry.—I am, etc.,

E. H. M. MILLIGAN, M.D., D.P.H.

Glossop, Sept. 18th.

### SANATORIUM TREATMENT.

SIR,—Your review on "sanatorium" treatment appearing in the *BRITISH MEDICAL JOURNAL* of August 28th (p. 397) is somewhat disconcerting to one who has been treating pulmonary tuberculosis at a sanatorium provided to deal with a population of 300,000 persons for the past eighteen years. We find here that all kinds of cases, almost without exception, do better at the sanatorium than when treated at home; home treatment may be considered as dispensary treatment without the fatigue of attending the dispensary. This must be true unless dispensaries use a method of treatment unknown in sanatoriums. The explanation of these contradictions would seem to lie either in something being wrong in the treatment given at the sanatoriums concerned or in some unknown factor working for the good of the patients at the dispensary.

It is possible that the sanatoriums do not carry out the correct treatment, which has been known at least since 1870, when Niemeyer of Tübingen published his *Lectures on Pulmonary Consumption* (the New Sydenham Society, 1870). It has been practised for many years at sanatoriums which have not become infected with the heresy of "graduated labour," but have followed the method of "graduated rest," as explained by myself in the *Lancet* of April 3rd, 1909. The former method probably came into vogue owing to the too successful filtering of cases at dispensaries and elsewhere, with the result that none but chronic or acute advanced cases find their way into sanatoriums, the time for whose successful treatment was missed, because dispensary or home treatment was thought sufficient. The cases suitable for a sanatorium should be recent and exhibiting symptoms of activity.

In order that success may follow, it is necessary that the following conditions be complied with: (1) intimate medical supervision; (2) rectal temperatures must be taken four times a day; (3) the patients must be kept in bed until their temperatures conform to normal, being at least as low as 36.6° C. before rising in the morning—I cannot enter further into this matter here; (4) provision should be made for separate rooms where necessary.

Dying patients should not be sent to sanatoriums as their presence is a detrimental psychological factor.

Three methods of treatment have recently come into vogue which emphasize the importance of rest: (1) artificial pneumothorax, (2) thoracoplasty, and (3) phrenectomy. These operations, which are hazardous and uncertain in their effects, are efforts to prevent movement of the affected lung, and become necessary because efficient sanatorium treatment with rest was not given earlier.

The diagnosis of tuberculosis should be made by a study of the history of the patient and a careful inquiry into symptoms, and not by the presence of physical signs and the finding of tubercle bacilli in the sputum. It is somewhat wearisome to be told that our results will, of course, be excellent if we treat cases where tubercle bacilli are not found; that has always been our contention. A case treated early soon becomes well and therefore difficult to diagnose; this, of course, is an advantage, the patient being then in the position of the remainder of his fellow citizens—that is, he is a person who has been infected but has no symptoms. It is perhaps unfortunate that we cannot as a rule both cure our patients and at the same time verify the diagnosis by finding tubercle bacilli; nor can we make sure by having an autopsy.

If only patients exhibiting symptoms be treated we make sure that we are only treating those who need it, and are not wasting time treating quiescent patients, who (as always) will continue for long periods to carry on their occupations without any treatment other than a few days in bed occasionally.—I am, etc.,

EDWARD E. PREST.

Arshire Sanatorium, New  
Cl. moock, Sept. 15th.

SIR,—There must be many of those interested in tuberculosis who have been waiting, like myself, to see what criticisms would be called forth by your review of the article on "The influence of sanatorium and dispensary treatment and housing conditions on pulmonary tuberculosis," recently published in the *Annals of Eugenics*. Nor have our expectations been disappointed. In the issue of the *BRITISH MEDICAL JOURNAL* for September 11th appeared a letter from Dr. F. R. Walters, and in that for September 18th appears a more damning indictment by Dr. J. R. Gillespie, both of these being medical men who have specialized in tuberculosis.

Most of your readers must have felt inclined at once to question the scientific value of Dr. Stocks's and M. Noel Karn's statistics when they read that patients who remained only fourteen days in a sanatorium were defined as "sanatorium treated." Dr. F. R. Walters, in his criticism, says "it is exceptional in this country to allot more than from three to five months to sanatorium treatment." I should have thought that in the present day it is generally admitted that anything less than a period of some six months is unlikely to have any material influence on the course of pulmonary tuberculosis. Speaking for Cheshire, I can say that a period of three to five months only is the exception rather than the rule. But in any case, to classify patients who have had only two weeks in a sanatorium as "sanatorium treated" is simply ridiculous.

Dr. Gillespie points out further fallacies, one of the most important (in his own view the most important) being the failure to differentiate "sputum-positive" from "sputum-negative" cases. Your editorial review states that "the memoir is based on an exhaustive study of the first 2,794 consecutive cases of undoubted pulmonary tuberculosis brought under the survey of the Belfast Tuberculosis Dispensaries." The most important step in the establishment of the diagnosis of pulmonary tuberculosis as "undoubted" is surely the demonstration of tubercle bacilli in the sputum. What value, then, can we give to the assertion that all these cases were cases of "undoubted tuberculosis" when the investigators themselves admit that "it was found impracticable to use the presence or absence of tubercle bacilli in the sputum as more than an adjunct in diagnosis, since the number of cases in which bacilli were sought for and found was relatively small" (italics mine), the percentages being given as 19 for males and 11.9 for females.

I think it is quite possible that the value of sanatorium treatment has been overestimated, and that we should preserve an open mind on the question. But it will require more carefully collated evidence than that published in *Annals of Eugenics* to prove that sanatorium treatment "is associated to a significant degree with inferior progress" of the patient afterwards, and that bad housing conditions, "as judged by . . . class of house, state of cleanliness . . . or overcrowding" have no influence on the patient's ultimate progress.—I am, etc.,

E. WEATHERHEAD,

September 19th. Tuberculosis Officer, Cheshire, North-East District.

### REGISTRATION OF NURSING HOMES.

SIR,—Your leader in the *BRITISH MEDICAL JOURNAL* for September 18th (p. 532) on the report of the Select Committee of the House of Commons draws attention to certain recommendations in that report, and visualizes the consequences if legislation is carried through to give them effect. But you fail to enlarge on two important aspects.

When talking or writing about "nursing homes" it is desirable to state exactly what is meant, as otherwise the popular idea that one is referring solely to places where a large number of patients can be received for medical, surgical, or maternity treatment holds the field. The Select Committee accepted as a definition:

"Any premises used, or intended to be used, for the reception of persons suffering from any sickness, injury, or bodily or mental infirmity for the purpose of providing such persons with nursing, where any payment or reward is made, or promised by, or on behalf of any person so received."

and desires even this definition to be amplified, as in its opinion it does not include premises for the reception of women in childbirth.

With regard to those places more generally accepted as being referred to as "nursing homes" you rightly conclude that the result of the legislation advocated will be to wipe out a large number of them, and you look to the voluntary hospitals to provide the necessary accommodation (as in public life one looks to the Government to end all our woes, so in medical life we seem to look to the voluntary hospitals to solve our problems). If this follows that will mean a further thrust for voluntary hospitals from being charitable places provided for indigent patients to become limited liability companies open to all. If this has to be it is just as well that the public and the medical profession should appreciate whither we are drifting.

But you touch very lightly on what would seem to be a more reprehensible part of the report. The Committee considers that doctors who receive single or two or more patients "are entering into a trade and into competition with others" and therefore lunacy inquiries and public to appreciate the permanently the border-line of mental soundness the earliest inducement should be offered to them to go where, alone or with a few others, proper medical supervision and assistance can be secured, whilst a home-like atmosphere is retained. Also, medical students are required now to have had some training in dealing effectively with such patients. Some hundreds of doctors now—and they could become thousands in the future—do receive one or more such patients, as well as those permanently unstable, into their family life. The result is most satisfactory to all concerned.

What will be the effect of legislation on these facilities, knowing what we do of registration, inspection, regulations, reports, and so on in other fields of public health? Will these doctors and their wives be content to submit their homes and home life to the inquisitorial control of a cold-blooded machine? If not, for such patients you suggest there will be hospital accommodation—that is, institutional treatment at an asylum, or State or voluntary hospital. And yet it is just that that these patients and their relatives loathe and will not submit to unless driven by poverty, as they seem certain that such will make them into chronic; also it is often quite unsuitable. Well then; what is to be done about it?—I am, etc.,

Hove, Sept. 20th.

R. ROWLAND FOTHERGILL.

#### MAN AS THE INTERMEDIATE HOST OF THE TAENIA SOLIUM.

SIR, Your correspondent Mr. E. J. H. Roth, in his article on the above subject (September 11th, p. 470), says: "It has not been found possible to discover a record of appearances which may be seen in radiograms when man becomes the intermediate host."

May I point out that such appearances in different patients have been described and illustrated with radiographs by the following authors: Sich (1905), Pichler (1911), Fischer (1912), Geipel (1913), Pursche, Köhler, Sauer, Stieda, and Brailsford.

A list of references are given in the paper, "The X-ray Diagnosis of Animal Parasites (Helminthes) in Man," which was delivered by me to the Electro-Therapeutic Section of the Royal Society of Medicine on January 19th, 1926, and can be found in the printed *Transactions* of the Royal Society of Medicine.—I am, etc.,

JAMES F. BRAILSFORD.

Edgbaston, Birmingham, Sept. 14th.

#### CANCER MORTALITY AND AGE RATES.

SIR, In your issue of August 28th (p. 367) there is an article by Dr. John Brown entitled "Comments and practical suggestions on Circular 426 (Cancer)."

In this article Dr. Brown compares the death rates from cancer between mining districts and residential and seaside towns, and suggests that the lower death rate amongst miners and their wives is due to "their active and strenuous life and their plain but efficient dietary." Might I point out that the discrepancy in the death rates

is in reality occasioned by the variation in the age rates in the two classes selected for comparison?

In mining and intensive industrial centres the proportion of persons over 40 is considerably less than in residential centres. In the two centres specifically mentioned by Dr. Brown—namely, Rhondda and Wigan, the proportion of persons over 40 is 249 and 270 per 10,000 of population respectively. In Hastings and Bath it is 415 and 399 per 10,000 of population respectively (census 1921).

At the period of highest cancer mortality (55-75) this discrepancy is still more marked. At the age period over 60 Rhondda has an exceptionally low proportion of persons, whilst Hastings has a correspondingly high proportion. A comparison between other intensive industrial centres such as St. Helens, Warrington, and Middlesbrough, and residential centres such as Bournemouth, Oxford, and Cambridge, shows similar results.

I should be interested to ascertain if Dr. Brown has further evidence, outside statistical, to support his view. Is there any confirmation of the statement, frequently made, that cancer is more prevalent amongst the well-to-do than the poor?—I am, etc.,

London, S.W.16, Sept. 16th.

E. HUDSON.

#### SUBACUTE APPENDICITIS.

SIR,—The letter in the *JOURNAL* of September 11th (p. 506) under the above heading from Sir John O'Connor raises several interesting points.

The increasing frequency of definite localized pain met with in the gastric and duodenal areas due to a cause quite remote from these regions—namely, a subacute appendix—has become crystallized into one of the most common difficulties and pitfalls which beset the general practitioner. The absence of any lesion where bismuth meals and x rays have been invoked, especially if coupled with undue retention of the test meal in the stomach, often confuses rather than clarifies the diagnosis.

On one point I differ from Sir John O'Connor, which, however, may be attributable to a more limited experience than his. Instead of finding increased pain and tenderness over McBurney's point I have generally found the opposite—namely, that discomfort, tenderness, and pain (even with fairly deep palpation) are present in an inverse ratio to that complained of in the regions referred to above. Needless to say, this greatly increases the difficulty of correct diagnosis.

For some time I have been on the look-out for a satisfactory explanation as to whether parallelism of structure, position, with undue or irregular innervation can in any way be responsible for the interference which takes place between a chronic appendix and the pylorus with the gastric symptoms which follow.—I am, etc.,

Arnscliffe, Westmorland, Sept. 13th.

D. M. MACDONALD.

#### THE MEDICAL PROFESSION AND LIFE INSURANCE COMPANIES.

SIR,—Is it not time to review the relations existing between the medical profession and life insurance companies?

A little while ago a patient of mine wished to take out a deferred policy on the life of his son, aged 9 years, with a certain London company. The company wrote to me, as his medical attendant, asking me to fill up a form containing a lot of questions bearing upon the family history of the proposer and his father, the answers to which were only known to me in my professional capacity. I took the form to my patient and with his permission answered the questions. One of the answers disclosed the fact of insanity in the family, and I now get a further letter from the company asking for information on this point.

Now this seems all wrong. If the company for its own interests requires this information it should address its queries to the proposer, or his father, if, as in this case, it is a child. In fairness to the company I must add that they paid me a fee of a guinea, but from one point of view this makes it worse, as they are paying the medical man to give away confidential information.

This brings me to another point—namely, the usual fee paid for examination. The fee remains the same as it was thirty years ago, though its purchasing power is much less, and, more important, the examination and report required are much fuller and more elaborate than they used to be.—I am, etc.,

Oporto, Sept. 11th.

W. A. MURRAY.

#### APPENDICITIS AND VEGETARIANISM.

SIR,—I was greatly interested in Mr. Hamilton Bailey's letter in the JOURNAL of September 18th (p. 545) as it is also my own conviction that diet has a close relationship to the incidence of appendicitis.

For a considerable period during the war I was responsible for the health of a large Arab population in Mesopotamia, and met with not a single case of appendicitis. The staple diet of these tribes was rice, dates, and other fruit. At the same time, among a much smaller British population in the same district, whose diet included tinned and frozen meat, numerous cases of appendicitis occurred.—I am, etc.,

R. J. McNEILL LOVE, M.S.Lond.,  
F.R.C.S.Eng.

London, W.1, Sept. 18th.

SIR,—I was much interested in Mr. Bailey's letter. A similar case occurred in my practice about three years ago. In this case the boy was about 15 years of age, and had been brought up on strict vegetarian principles. The appendicitis was acute and the operation only just in time to prevent perforation.—I am, etc.,

JOSEPH A. PARKES, M.B., Ch.B.

Bristol, Sept. 21st.

#### Obituary.

Dr. JAMES CYRIL DALMAHOY ALLAN, who died in Hong-Kong on September 8th from infective endocarditis, received his medical education at Edinburgh, where he graduated M.B., Ch.B. in 1905, obtained the diploma of tropical medicine in 1907, and proceeded M.D. in 1911 with distinction. After graduation he acted as house-physician under the late Dr. G. A. Gibson in the wards of the Infirmary, and subsequently obtained the appointment of senior house-surgeon to Mr. Hogarth Pringle at the Royal Infirmary, Glasgow. In 1908 he became medical officer to Christmas Island, where he remained for two years, when he removed to Hong-Kong. A colleague writes: "On looking back at the old days in the university, one remembers an outstanding figure that strode smiling and cheerful through his classes and seemed to absorb facts and pacify examiners without apparent effort. His quick and ready mind went straight to the essentials, and many a slower-brained colleague was grateful for some point of difficulty cleared up by a short succinct explanation or demonstration. He had a host of interests besides the mere routine of class work. The Royal Medical and the Dialectic Societies were channels for the outflow of his superabundant energies, and under his stimulating guidance the English Public Schools Club took on a new lease of life. As a house-physician he ranked high, and he took to Christmas Island a knowledge of his profession that that small islet will probably never see equalled. A remarkable spontaneous demonstration of regret signaled his departure from the island, all the inhabitants, to the humblest Chinese coolie, uniting to do him honour. The value of his work was recognized in high places, as evidenced by his return to the island, for a brief period after the war, as governor. Allan arrived in Hong-Kong speaking Cantonese as easily as he did English. His practice among Europeans and Chinese rapidly increased, and he achieved notable success as a surgeon. With his strong sense of humour, his undeviating honesty, and a certain streak of fatalism that ran through his character, he found much about the Chinese to appeal to him. His interest in the country was profound, and he made several pilgrimages to the remote interior. On one occasion, in company with his faithful Chinese friend and body-servant, he walked over a thousand miles overland. During the tour he spoke no word of English and adopted the native costume. During the war he was at first

attached to a battalion in France, and later was transferred to the staff. For gallantry in the field he was awarded the Croix de Guerre by the French Government. It was hoped by many that he would elect to stay in this country, but his tastes and family traditions pointed the way eastwards, and the glamour of the Orient held him in its spell. He leaves us with a golden memory of a vivid arresting personality: one who was a born healer of the sufferings and sorrows of mankind. His generous heart had a genius for friendship, and his many friends adore him, rejoicing in the charm of his infinite variety. Breezy, hearty, joyous, a jest was never far from his lips, a kindly greeting ever in his eyes."

#### The Services.

##### INDIAN MEDICAL SERVICE.

###### STUDY LEAVE RULES.

WE have received from the Director-General, Indian Medical Service, a copy of revised study leave rules for the I.M.S. Army Instruction, India, B 206 of July 27th, 1926, published as Army Notification No. 890 in the *Gazette of India* of July 10th.

1. Study leave may be granted on the recommendation of the D.G.I.M.S., by the Government of India, or by local governments who may delegate their powers to the High Commissioner for India.

2. The amount of such leave which may be granted is one-twelfth of an officer's service qualifying for leave, up to a maximum of twelve months during an officer's service.

3. This leave may be taken at any time, but an officer who, after taking study leave, retires, on any ground except ill health, within three years of the date of his return to India, will be liable to forfeit all benefits which he has received in respect of that study leave, and to refund any additional pay or allowances received for such leave.

4. The minimum period of study is two months.

5. The minimum period of leave granted solely as study leave is six months.

6. Study leave can be combined with any other leave, provided that the period of study is not less than two months.

7. Except as provided in Rule 8, an officer should submit his application for study leave through the prescribed channels, stating the course or courses of study he proposes to undergo, the institution where he proposes to study, the dates of beginning and ending of the course, and the examination he proposes to undergo.

8. Officers on leave who wish to convert part of their leave into study leave must apply to the High Commissioner for India. If they wish to leave for purposes of study they must submit evidence of having obtained the approval of the High Commissioner in India to their application for extension and to the course of proposed study.

9. An officer may undertake a course of study during leave on average pay, and draw study allowance therefor, provided that study allowance is not drawn for a total period of more than twelve months during his whole service.

10. Study allowance is at present fixed at twelve shillings a day in the United Kingdom, £1 on the Continent of Europe, and £1 10s. in the United States. No allowance can be drawn until the officer has submitted the certificates required by Rule 12. The allowance is not admissible to an officer who retires at the expiration of his leave without returning to India, and may be retrenched, under Rule 3, if he retires within three years of his return. A period of vacation, not exceeding fourteen days, between two courses of study, may be counted as study leave. No course of study will be recognized as study leave for allowance or any other purpose unless the course of study has been approved in accordance with Rules 7 and 8.

11. The rate of pay admissible during study leave is half average pay, subject to the prescribed minima and maxima.

12. On completion of a course of study leave a certificate in the proper form, together with any certificates of special study, must be submitted to the High Commissioner for India.

13. Study leave will count as service for promotion and pension, but not for further leave. It will not be counted in calculating the aggregate amount of leave which an officer may take during his service.

The above rules apply also to officers in temporary civil employ, and in military employ, with a few variations, as follows:

2. The period of study leave allowable is one-twelfth of pension service.

6. The total period of all combined leave granted, in the first instance, will not exceed one year.

7. Such officers should apply to the Under Secretary of State, Military Department, India Office, instead of to the High Commissioner.

11. The rate of pay admissible during study leave is the rate of pay admissible under military leave rules.

As the above notes are considerably condensed from Instruction No. 206, all officers who propose taking study leave should carefully study the original Instruction.

## KING'S HONORARY PHYSICIAN.

HIS MAJESTY has approved the  
Sir Matthew H. G. Fell, K.C.I.  
Medical Services, to be Honor  
ary from June 3rd, 1926, in  
General Sir William Lleshman,

General  
Army  
with  
tenant-

## EXCHANGE OF NAVAL MEDICAL OFFICERS.

ADMIRALTY Fleet Order No. 2607 states that a surgeon-commander R.N., is required for service as senior medical officer, Flinders Naval Depot, in exchange for a surgeon-commander, Royal Australian Navy. The depot hospital includes a theatre where all major surgical operations are undertaken, and the officer will be required to be an operating surgeon. The appointment will carry assisted passages for wife and children, and the Australian authorities state that information as to the prospects of obtaining a house can be communicated later. Early application should be made for this appointment through the usual Service channels. The position of officers lent for service in the R.A.N. is in all respects equivalent to that of officers who serve continuously in the Royal Navy, with whom they will be considered equally for promotion and appointment.

## Medical News.

DR. ANDREW BALFOUR, Director of the London School of Hygiene and Tropical Medicine, will attend the fiftieth anniversary celebration of Johns Hopkins University, Baltimore, next month, and deliver an address at the formal opening of the new building of the School of Hygiene and Public Health of that university.

THE opening function of the winter session at the Middlesex Hospital Medical School will take place at the Queen's Hall, Langham Place, on Friday, October 1st, at 3 p.m. Professor T. Yeates will deliver the introductory address, after which the Archbishop of Canterbury will distribute the prizes. The annual dinner of past and present students of the school will be held the same evening, at 7.30, at the Savoy Hotel, with Mr. Victor Bonney in the chair.

THE annual prize distribution at St. George's Hospital Medical School will be held on October 1st, at 3 p.m., in the board room of the hospital, when the inaugural address, entitled "Doctors and the public," will be delivered by Dr. E. Graham Little, M.P. The annual dinner will be held at the Hyde Park Hotel at 7.45 on the same day, with the Right Hon. C. C. Craig, M.P., in the chair.

AT the opening of the winter session of the London (Royal Free Hospital) School of Medicine for Women, Hunter Street, W.C., on Friday, October 1st, at 5.30 p.m., the introductory address will be given by Sir Walter Fletcher, K.B.E., M.D., F.R.S., Secretary of the Medical Research Council.

AT the opening of the eighty-fifth session of the School of Pharmacy of the Pharmaceutical Society of Great Britain on Wednesday, October 6th, at 3 p.m., the inaugural sessional address will be delivered by Dr. James F. Tocher, of the University of Aberdeen.

AN autumn course of lectures at the Hospital for Sick Children, Great Ormond Street, W.C.1, will commence on Thursday, October 7th, at 4 p.m., when Dr. Cockayne will deal with "Rickets as it is seen to-day."

A NEW course of post-graduate study at the National Hospital, Queen Square, Bloomsbury, will be held from October 4th to November 26th. It will consist of out-patient clinics, clinical lectures and demonstrations, lectures on the anatomy and physiology of the nervous system, demonstrations on the pathology of nervous system, and clinical demonstrations on methods of examination. The fee for the course, including the pathology demonstrations, is £5 5s., and for those holding perpetual tickets £3 3s.

A COURSE of post-graduate lectures will be given at Ancoats Hospital, Manchester, on Thursdays at 4.15 p.m., beginning on September 30th, when Mr. Harry Platt commences a series of six lectures on the treatment of common injuries. Three lectures on tonsillectomy will be given by Mr. F. Holt Diggle on November 11th, 18th, and 25th. There is no fee for the course, and all medical graduates are cordially invited. Tea will be served at 3.45 p.m.

A COURSE of twelve lectures will be given on Sunday afternoons, commencing October 3rd, at 3.30, at The Guildhouse, Eccleston Square, S.W.1, on the contribution of science to human life. Sir Richard Gregory (editor of *Nature*) will speak on the worth of science at the first meeting, and Dr. Bernard Hollander on the sound and unsound mind at the second. Sir George Newman will lecture on the contribution of medical science to human life, on December 5th. Further information may be obtained from the honorary secretary to the Guildhouse Advisory Board, 2, Rosslyn Mansions, Goldhurst Terrace, N.W.6.

DR. JOHN RUDD LEESON, J.P., senior consulting physician to St. John's Hospital, Twickenham, is the Charter Mayor of the newly incorporated Borough of Twickenham, and as such attended the celebrations on September 22nd.

AT the meeting of the Society for the Study of Inebriety, to be held in the rooms of the Medical Society of London, 11, Chandos Street, Cavendish Square, on Tuesday, October 12th, at 4 p.m., Dr. J. D. Rolleston will read a paper on alcoholism in classical antiquity.

THE Biochemical Society has arranged the following provisional programme of meetings for the session 1926-27: Saturday, October 9th, Cambridge; Monday, November 8th, St. Thomas's Hospital, S.E.1; Monday, December 6th, Imperial College, S.W.7; Monday, February 7th, 1927, Lister Institute, S.W.1; Friday, March 18th, University College, W.C.1.

A COURSE of practical demonstrations on deep x-ray therapy in the treatment of tumours at the Beaujon Hospital, Paris, will begin on October 5th, and continue on following Tuesdays; while on Friday mornings from October 8th another course on electrical diagnosis and treatment will be given at Dr. Aubourg's laboratory. Further information may be obtained from Dr. Aubourg at the Beaujon Hospital. The demonstrations (which will be delivered in English, if desired) are free to practitioners and students.

THE People's League of Health will be represented at the conference convened by the International Union against Tuberculosis, to be held in Washington, U.S.A., from September 30th to October 3rd, by the following members of its medical council: Sir Robert Philip, Sir John Lunn-Thomas, Professor S. Lyle Cummins, and Dr. Edward Hope.

POPULAR talks on travel, science, and invention will be given in October and November, with experimental demonstrations or lantern slide illustrations, in aid of King Edward's Hospital Fund for London. The series, which commences with "Seeing by wireless," by Mr. H. L. Baird, at the Royal Institute of British Architects, on October 7th, at 5 p.m., will include talks on subjects as diverse as aviation, artificial production of the human voice, liquid air, the Sahara, and refrigeration. Tickets, price 2s. 6d. and 5s., or serial tickets 12s. 6d., may be obtained from the Secretary, King Edward's Hospital Fund for London, 7, Walbrook, E.C.4, or at the doors.

THE Council of Epsom College is about to award one of the Leopold Salomons Entrance Scholarships of £50 a year which were established "as a slight recognition of the splendid work of the medical profession carried on during the war." Candidates must be sons of legally qualified members of the medical profession and be unable to enter Epsom College without the help of this scholarship. They must have reached 11 years of age and be under 14 on January 1st last, and show a standard of education adequate for their age. Forms of application and full particulars will be supplied by the Secretary of the College, 49, Bedford Square, W.C.1, where applications must be sent not later than the morning of October 6th. The Council will also shortly award a special St. Anne's Home scholarship of £52 a year, tenable for about five years, to the orphan daughter of a medical man who was in independent practice in England or Wales for not less than five years. Only those are eligible as candidates who were fully 10 years of age and not over 12 years of age on May 1st last. Forms of application can be obtained from the Secretary.

THE first all-Russian ophthalmological congress will be held at Moscow from September 27th to 30th.

THE first German congress for combating tobacco smoking by young persons was held at Düsseldorf from August 7th to 9th, when papers were read on physical exercise and smoking, and smoking among the youth of the working classes. The use of tobacco by children in Holland has recently grown to an alarming extent. A recent investigation has shown that smoking is practised by 30 per cent. of boys aged 6, by 50 per cent. of boys between 9 and 10, and by 88 per cent. of those over 11 years of age.

A CHAIR for the history of medicine has recently been founded at the University of Louvain, with Dr. Tricot-Royer, president of the International Society of the History of Medicine, as its first occupant.

DR. MAURICE FAURE, President of the Société Médicale du Littoral Méditerranéen, informs us that his society has organized a visit of doctors from different countries to the French Riviera for the purpose of acquainting them with the therapeutic resources of that region. The journey will take place between December 15th and 24th, and will include visits to Hyères, St. Raphael, Cannes, Grasse, Venice, Nice, Beaulieu, Mentone, Monte Carlo, and Monaco. The programme and full particulars can be obtained from the Office Français du Tourisme, 55, Haymarket, London, S.W.1.

## Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **The EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1.**

**ORIGINAL ARTICLES** and **LETTERS** forwarded for publication are understood to be offered to the **BRITISH MEDICAL JOURNAL** alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring **REPRINTS** of their articles published in the **BRITISH MEDICAL JOURNAL** must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs.

All communications with reference to **ADVERTISEMENTS**, as well as orders for copies of the **JOURNAL**, should be addressed to the Financial Secretary and Business Manager.

The **TELEPHONE NUMBERS** of the British Medical Association and the **BRITISH MEDICAL JOURNAL** are **MUSEUM 9561, 9562, 9563, and 9564** (internal exchange, four lines).

The **TELEGRAPHIC ADDRESSES** are:

**EDITOR** of the **BRITISH MEDICAL JOURNAL**, *Aitiology Westcent, London.*

**FINANCIAL SECRETARY AND BUSINESS MANAGER** (Advertisements, etc.); *Articulate Westcent, London.*

**MEDICAL SECRETARY**, *Medisecra Westcent, London.*

The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 4737 Dublin), and of the Scottish Office, 6, Drumsheugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 4361 Central).

### QUERIES AND ANSWERS.

#### PRURITUS.

"W. A." asks for suggestions in the treatment of a patient aged 52, who suffers from continual pruritus all over the body, most pronounced on the palms of the hands and increased after meals. The condition started in September, 1925. The urine is normal; there is no evidence of venereal disease, past or present. The skin is hardened and thickened. Mineral and sea baths, arsenic, and light diet have alike failed to give relief.

#### INCOME TAX.

##### *Production of Detailed Accounts.*

"H. E. E." has been asked by the inspector of taxes to supply him with copies of accounts—showing gross receipts and expenses—as a condition (apparently) of granting the depreciation allowance for a motor car; the request has been complied with, but is there any reason why it should be made on a depreciation claim?

\* \* There is just this technical ground, that the depreciation allowance is not due if cost of renewals (not "obsolescence" claim) has been included in the accounts, but it may be that the inspector's request would, in any event, have been made before long. "H. E. E." is entitled for 1926-27 only to the depreciation allowance on the value of the car as at April 5th, 1926, calculated on the basis of writing down the value of the car at the depreciation rate. "H. E. E." should bear in mind that when he renews his car he can submit an obsolescence claim—that is, allowance of the renewal cost less the depreciation actually allowed on the car.

##### *Assessments.*

"W. H. K." has been separately assessed under Schedule E in respect of the emoluments of an appointment; the fees have been included in the Schedule D return as part of the general profits of his practice.

\* \* We think that the separate assessment was made without knowledge of the circumstances, and that it will be discharged by the inspector of taxes on receipt of an explanation from "W. H. K."

"F. R. W." who practises in the Irish Free State, explains that he has recently been called upon to pay £12 odd, an amount assessed upon his father, since deceased, for 1924-25, and that if his father had "appealed against this assessment within the statutory time limit of twenty-one days he had ample allowances to counterbalance this amount."

\* \* If "F. R. W." refers to the statutory "allowances" for individuals (£135 or £225), wife, assurance, etc., he can claim repayment within six years from April 5th, 1925, but if he refers to a claim for a reduction of the gross amount assessed any appeal is now outside the time limit and he has no legal claim to redress.

#### *Replacement of Car.*

"X. Y. Z." had a two-seater 10-h.p. car (cost £475), which he sold in 1924 for £90, purchasing a four-seater 14-h.p. car of similar make for £375. What can he claim?

\* \* He can claim as an expense of the year 1924 the then cost of a 10-h.p. two-seater car less £90. This may seem somewhat inadequate, but the difficulty is that part of the expenditure incurred in 1924 went in improvement, and as such has to be regarded as capital outlay.

### LETTERS, NOTES, ETC.

#### SPONTANEOUS DISAPPEARANCE OF THE ARCUS SENILIS.

DR. J. W. TOMB, O.B.E. (Asansol, Bengal, India), writes: An Englishwoman, married, aged 60, was attacked with influenza in 1918, from the effects of which she did not fully recover. Her relatives and friends stated that prior to her illness she had been more alert and vigorous than the average person of her age. When I saw her a year later she was remarkably pale, anorectic, as well as somnolent and apathetic; she also suffered from pronounced anorexia. Examination did not reveal any very definite physical symptoms, except moderate anaemia and a slight degree of pyorrhoea. A distinct arcus senilis was visible in the lower semicircle of each iris. Treatment of various kind for the anorexia and anaemia was without effect, the patient continuing in the state described above for over twelve months. At the end of that period all teeth were extracted on her dentist's advice and artificial teeth provided. Following this procedure and without any further treatment, the somnolence and apathy gradually disappeared, and the patient again becoming alert and vigorous, so that when examined by me three years later she appeared many years younger than on her previous visit; the arcus senilis, in the meanwhile, had completely disappeared from both eyes.

#### TUBERCULIN DISPENSARIES.

DR. ANNIE MCCALL, Chairman and Director, Clapham Maternity Hospital and Affiliated Institutions (London, S.W.), writes: Will you very kindly allow me to ask, through the medium of your columns, if perchance there is now a tuberculin dispensary in Brighton, where a patient going out from Rudgwick Sanatorium may receive treatment with tuberculin on the intensive system, as taught by Dr. Camac Wilkinson in 1910 and following years? I can hardly imagine a place of the size and importance of Brighton not having a public tuberculin dispensary, and there surely must be some of the many doctors there who are proficient in the method, but I cannot find any one who is known to be an expert in this treatment.

I personally have followed out his method of treatment ever since the Clapham Tuberculin Dispensary was opened in April, 1911, and am more than ever convinced that, up to the present time, no other treatment can give anything like such good results, and I have been working at Rudgwick Sanatorium ever since 1893. If this treatment is begun early enough about 99 per cent. recover completely, and that without having to give up their daily work, which is so important. In London, now that Dr. Wilkinson has returned, this early treatment may be obtained at 32, Fitzroy Street, Fitzroy Square, Tottenham Court Road, W.C., on Mondays and Thursdays, 9 to 11 a.m., and doctors are invited to come and learn it. Other towns should surely be able to work out such a system, so that patients everywhere may get the benefit.

#### JOHN HILTON.

DR. RICHARD GILLIARD (Willesden Green, N.W.) writes: Sir Arthur Keith, the great anatomist, in an address in the **BRITISH MEDICAL JOURNAL** to those entering the profession (September 4th, p. 409), avers that "every student should get to know Hilton's *Rest and Pain*, not only for what he has to say, but also for the way he says it." Besides that classical book, we are aware, as well, of the exquisite, unrivalled anatomical dissections in the Guy's Museum, representing "the day's work." We know, too, that John Hilton was surgeon to Guy's, President of the Royal College of Surgeons, and received other "decorations"; but is there any material to reveal the personality, the man behind it all? Is there a portrait, was he in love, did he marry, and whom? Was he acquainted with sorrow? Joseph Towne, who realized his dissections, was an artist; was Hilton an artist, too? It is said that, as a lecturer, "he had an unfortunate way of irritating students." There may be light here, for Landor, the perfect author and creator of *Rose Aylmer*, quarrelled—most of all with himself. After leaving Guy's, Hilton practised in the City, apparently toiling to the age of 74. Perhaps he had not been prosperous, and one would not like to think of Hilton as a "successful" Mendelssohn. We may speculate, as his thoughts wandered to his Alma Mater, and think—

No exile's dream was ever half so sad.

And, I return to my question, who was John Hilton?

#### VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 42, 43, and 47 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 44 and 45. A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 156.

# A British Medical Association Lecture ON THE DIAGNOSIS AND TREATMENT OF PLACENTA PRAEVA.

GIVEN TO THE WINCHESTER DIVISION ON JULY 7TH, 1926,

BY

J. BARRIS, F.R.C.P., F.R.C.S.,

PHYSICIAN ACCOUCHEUR, ST. BARTHOLOMEW'S HOSPITAL.

THE subject of the diagnosis and treatment of placenta praevia is not only one of the greatest practical importance, but one much debated and upon which opinion is still divided.

## DIAGNOSIS.

It is first necessary to ascertain whether the blood comes through the cervical canal or from disease of the lower genital tract—as, for instance, carcinoma of the cervix. This can be determined by examination with the finger and with the speculum. If the blood be found to come through the canal we have then to decide between a diagnosis of accidental haemorrhage or of placenta praevia.

The presence of placenta praevia may be conjectured if the haemorrhage has been repeated owing to the gradual stretching of the lower uterine segment and resultant separation of it from the placenta. The existence of a malposition of the foetus, or the finding of the foetal head too high or unengaged, more especially in a primigravida at or near term in whom the pelvis is not contracted, is also suggestive of the condition. It is possible that if the woman is very thin the placenta may be palpable as a boggy mass at the pelvic brim on abdominal examination, or that the head may be felt more clearly one side than on the other. An unusually loud uterine souffle over this area has sometimes been noted. Vaginal examination may reveal a spongy resistance in the fornices obscuring the presenting part. The absence of albuminuria is also suggestive; it is much more commonly present in accidental haemorrhage, although several cases have now been recorded in which this condition has been found in association also with placenta praevia.\*

If, therefore, there is bleeding but no malposition, if the head is engaged and albumin is present, a diagnosis of accidental haemorrhage is suggested. If, on the other hand, the bleeding has been repeated, the head is high, there is a malposition, and albumin is absent, placenta praevia is the more probable diagnosis. But none of these symptoms or physical signs is of itself sufficient to enable us to establish a diagnosis. The only certain way to diagnose placenta praevia is to feel the placenta through the cervical canal; if then the spongy placenta can be felt the diagnosis is certain. Blood clot or a vesicular mole may be mistaken for the placenta; the former is distinguished by its friability and the ease with which the finger can be pushed through it. A vesicular mole is more difficult to distinguish, but the bleeding usually occurs far earlier in pregnancy; the undue size of the uterus in relation to the period of amenorrhoea and the inability to feel a foetus on abdominal palpation or to obtain internal ballottement serve to distinguish between the two conditions. It is rare that the cervix will not admit the finger; but if the cervix is closed, or if when open the examining finger cannot reach the placenta, the diagnosis must still remain in doubt.

Now early diagnosis is an essential part of the treatment of placenta praevia. It has therefore been suggested that if, during the later weeks of pregnancy, the cervix be closed, an attempt should be made to establish the diagnosis by passing a metal dilator through the canal, for if on withdrawing it bleeding occurs the presence of the placenta can certainly be inferred. In almost all cases, however, the cervix will allow the finger to be passed if care and gentleness are employed.

## TREATMENT.

We may first review the principles upon which the treatment must be based.

Nature's method of arresting bleeding from the placental site is threefold. It consists of thrombosis of the uterine vessels, and contraction and retraction of the uterine muscle. Of these thrombosis does not play a determining part, and contraction is effective only when the muscle is gripping the blood vessels, but is ineffective during relaxation. Retraction is the important factor, for the shortening of the muscle fibre is permanent. Now retraction can only be efficient if the uterus is empty. It therefore follows that the only efficient way to stop the bleeding is to terminate the pregnancy.

If this principle be accepted the next point that arises is whether, once the diagnosis is made, the pregnancy should be terminated forthwith, or whether we are justified in temporizing in order to increase the viability of the foetus. In this connexion it is necessary to take into account that permanent arrest can only be assured by complete retraction, and that until the woman is delivered she is open to the risk of further haemorrhage as the cervix and lower segment dilate, and so cause further separation of the placenta from the low placental site; nor is it known to what extent a further haemorrhage may be. Therefore a temporary cessation of bleeding must not be allowed to lull us into a false sense of security, for at any moment a fresh bleeding, and even one which may prove fatal to the mother, may occur.<sup>2</sup> Further, the life of the foetus is always precarious, for not only is it usually premature, but it is liable to die of asphyxia during the process of delivery, and is sometimes weakened by loss of blood through injury to the placenta and the foetal blood vessels. It is not right, therefore, to risk the mother's life by delay in order to give the child a better chance, and in deciding upon the treatment the interests of the mother must be our first consideration. It follows upon this that once the diagnosis is made the pregnancy must be ended, and ended at once; hence an early diagnosis is of the utmost importance.

We have now to consider the method of terminating the pregnancy. Our choice of method must be guided by a consideration of the following points. The haemorrhage must be arrested temporarily during the process of delivery by means of pressure of some sort upon the exposed placental site; the delivery should be carried out at such a time as the patient is in a condition in which she will be best able to bear it, and conducted in such a manner that will entail a minimum of shock, of further haemorrhage, and of injury to the maternal soft tissues. It is our intervention, therefore, which must be prompt, but the actual delivery must be slow. The arrest of the haemorrhage and the delivery of the patient are two distinct and separate points. To do both at the same time is a confusion of aim and of ideas. There is everything to be gained by delay after the bleeding has been arrested, for not only is the patient given time to recover from her shock, but she is less exposed to the risk of further haemorrhage and laceration if the foetus is not rapidly extracted, but is allowed to be expelled subsequently by uterine contractions. The foetus also is less exposed to overmoulding of the head and to the other complications which rapid delivery entails.

The temporary arrest of the haemorrhage and the subsequent delivery of the patient may be effected by means of (a) rupturing the membranes and the application of a binder; (b) vaginal plugging and binder; (c) traction on the head if a vertex presentation; (d) the insertion of a hydrostatic bag; (e) version and plugging by the half-breech. The choice of which particular method is best suited for the individual case must depend, not only upon the size of the cervix and the position of the placenta, but also, and primarily, upon the condition of the mother, the amount of blood which she has lost already, and the probable amount of further haemorrhage which will be involved during the process of the delivery.

Except for the cases of placenta praevia which can be described as slight, in that the patient's condition is good, little blood has been or is likely to be lost, and in which the cervix is well dilated, uterine contractions are strong,

and the placenta is not easily reached—except for such "slight" cases the patient requires so much attention, so much time and care, that institutional treatment in either a hospital or nursing home is essential.

We come now to a review of the various methods of treatment and to their application, having regard to the general principles which we have just considered.

#### *Rupture of Membranes and Application of Abdominal Binder.*

The object of this method is to bring pressure upon the placental site by allowing some of the liquor amnii to escape so that the uterus may drive down the presenting part and compress it against the lower uterine segment. It is a simple method which can be carried out, not only easily, but with little risk of causing fresh bleeding during the necessary manipulation. It will clearly be suitable if strong pains are present, if the cervix is well dilated—that is, the patient is in active labour—if the placenta is not over the internal os, if the membranes can be reached easily, and the lie of the foetus is longitudinal. In such cases it is the ideal treatment. But its employment must be limited to such cases, as it is unsuitable if the cervix is not dilated and pains are absent, for an attempt to rupture the membranes might then result in causing further haemorrhage or stripping up of the membranes only; also, in the event of being successful in rupturing the membranes, it would be by no means certain that uterine contractions would follow. No pressure would then be exerted upon the placental site, and, if too much liquor amnii escaped, version, if thought desirable, might not be possible to effect.

In the presence of uterine contractions and an open cervix it is wiser not to delay the rupture of the membranes for too long if the margin of the placenta can be felt fairly easily, for further haemorrhage is likely to occur as the cervix continues to dilate, and so to bring about further stripping up and exposure of the placental site.

Schweitzer<sup>7</sup> states that out of 333 cases of placenta praevia 22 partial cases were treated by rupture of the membranes with no maternal mortality; and according to Bourne,<sup>1</sup> of 17 cases treated at Queen Charlotte's Hospital by rupture of the membranes, with or without an abdominal binder, there was also no mortality of the mother. The foetal death rate for both marginal and lateral cases treated by rupture of the membranes was only 26 per cent., including all children irrespective of their maturity. The method is, therefore an ideal one, but it is necessarily limited in its application to a certain group of cases in which strong pains are present, the cervix is dilated, the lie is longitudinal, and the placenta is not easily reached. For these it is all that is required and is to be strongly recommended; it entails little interference and the results are good. If the vertex is presenting, a firm abdominal binder is applied; if the breech is presenting, a leg should be brought down after rupturing the membranes, and in either case the labour is then allowed to proceed naturally. But for other cases in which the placenta is easily felt and in which uterine pains may be absent, some other method must be employed.

#### *Vaginal Plugging.*

The temporary arrest of the haemorrhage is here effected by the combination of pressure of the vaginal plug from below and the abdominal binder from above. The method acts further by stimulating uterine contractions, and allows the cervix to dilate. It is advisable first to rupture the membranes, or uterine contractions are not certain to come on soon. It must be carried out under the strictest precautions against sepsis, and it requires an anaesthetic.

At first sight the method presents many advantages. It entails no intrauterine manipulations, and its application is not so likely to bring on further bleeding as is any method which entails an instrument or the fingers being passed through the cervical canal; the size of the os is immaterial, and there is not the same danger of lacerating it or the lower uterine segment; no special apparatus is required, no damage is done to the foetus, and the mother is given time to recuperate if she is collapsed from a

previous haemorrhage. But, on the other hand, the method possesses many disadvantages. Uterine contractions do not necessarily follow within a reasonable time; the plugging may have to be removed and renewed, the risk of sepsis is extreme; the tight plug may cause lacerations of the cervix and vagina, and bleeding may occur above the plugging. Moreover, it demands a set surgical procedure under anaesthesia in order to be carried out effectually. It cannot be carried out effectually by the practitioner unaided, and if not so carried out it is not only useless but it is a positive source of danger from the risk of sepsis and of bleeding above the plugging. I know of patients who have died as a result of both of these causes from ineffectual plugging.

The disadvantages of plugging, from the risk of sepsis and of internal haemorrhage, far outdo the advantages, and its use in placenta praevia is not only inadvisable but is strongly to be deprecated, unless it be as a very temporary expedient. Its use in accidental haemorrhage is another matter. Jellett,<sup>5</sup> quoting his experience at the Rotunda Hospital, Dublin, concurs in this view. He states definitely that it should not be employed in placenta praevia except in the rare instances where the cervix is not large enough to admit the finger; he regards it as a grave danger, and if it is necessary to use it, it must be removed within a few hours. Bourne<sup>1</sup> gives the following figures as the results obtained by plugging the vagina for placenta praevia at Queen Charlotte's Hospital between 1916 and 1922:

| No. of Cases. | Variety. | Mother Recovered. | Mother Died. | Good. | - Child Stillborn. | Child Died. |
|---------------|----------|-------------------|--------------|-------|--------------------|-------------|
| 8             | Central  | 6                 | 2            | 0     | 7                  | 1           |
| 14            | —        | 14                | 0            | 1     | 7                  | 5           |
| 17            | Lateral  | 15                | 2            | 6     | 9                  | 4           |
| 2             | Unstated | —                 | —            | —     | —                  | —           |

This shows a total mortality (maternal) of 9.7 per cent. of 41 patients treated by plugging the vagina.

#### *The Hydrostatic Bag.*

The bag is inserted into the uterine cavity, the membranes having been ruptured. Gentle sustained traction upon it arrests the haemorrhage by pressure upon the exposed placental site. It further helps dilatation of the cervix, and at the same time stimulates uterine contractions. The results of its use are claimed to be more favourable to the foetus than by pressure with the half-breech.

Its disadvantages are that it is not always available in case of emergency, or if available it may leak, as it is liable to perish. It also tends to displace the presenting part, and so may bring about complications from a malpresentation. Not uncommonly it is expelled from the uterus without the presenting part coming down and without fully dilating the cervix, so that there is a loss of continuity of pressure upon the placental site and the recurrence of bleeding above the bag. It further has the drawback that considerable haemorrhage may accompany its insertion. Nor does the medical attendant feel secure after its insertion, since it may be expelled too soon and bleeding occur above it. This entails, after its insertion, the constant attention and presence of the practitioner. For these reasons, although it is a good method provided the patient is in an institution, it is not suitable for the emergencies of general practice. It must be borne in mind also that it requires an anaesthetic, and should therefore not be used unless the patient is in a condition to stand a further anaesthetic should other manipulations be required, either to arrest haemorrhage or to deliver the foetus, after the bag has been expelled, such as the forceps or version. In 6 cases of placenta praevia treated by the bag at St. Bartholomew's Hospital it was expelled before the cervix was fully dilated in every case, thereby necessitating the use of other additional methods subsequently.

#### *Plugging by the Half-Breech.*

In this method the bleeding is controlled by the pressure of the foetus itself against the placental site. Steady but gentle traction on the leg will not only control the bleeding

# PLACENTA PRAEVA.

OCT. 2, 1926]

but will also, as in the case of the bag, help to dilate the cervix and stimulate uterine contractions. If the breech is not already presenting it will be necessary first to perform version. The best way to do this is to do external version and then to bring down a leg, as it entails less manipulation, and so less risk of accompanying haemorrhage from causing further separation of the placenta. Plugging by the half-breech requires that the cervix should be dilated enough to admit two fingers, but it is extremely rare that this criterion is not present by the time we are asked to see the patient. An essential part of the treatment is that, having performed an external version and brought down a leg, the labour should then be left to Nature in order to prevent laceration of the cervix and complications with the foetus.

The method possesses certain great advantages, for no special apparatus is required and an anaesthetic is often unnecessary. Moreover, continuous pressure upon the placental site is definitely secured. If the mother's condition is not good it is advisable, in that it not only stops the bleeding but it allows the mother to recover and to deliver herself naturally later on. It is undoubtedly the best available method in the majority of cases, and is especially applicable to the conditions of general practice. Jellett<sup>2</sup> advises version and bringing down a leg as the best method. He states that it requires two conditions:

(a) the membranes must be unruptured to allow two fingers; (b) the os must be big enough to admit two fingers. He finds the first is practically always present, and the second in "more than 99 per cent. of cases." In the rare instances where it is not he recommends that the vagina may be plugged for a few—but only for a few—hours, as he regards the pack as too dangerous. The os will then be sufficiently open to allow a leg to be brought down. He found in a collected series of 264 cases of placenta praevia so treated that the maternal mortality was 5.3 per cent., including moribund patients, and 3 per cent. only if these were excluded.

In Schweitzer's<sup>3</sup> series about 40 per cent. were treated by a hydrostatic bag where the condition of the mother was good and the foetus was sufficiently mature. He noted that a fairly copious loss of blood attended its use, but it gave a better chance to the child. He considers that if the mother has already lost considerably version is much safer for her, though attended with a high foetal mortality. His results were 3.8 per cent. maternal mortality if the bag was used, and 6.6 per cent. if version was employed, but he specially states that this was selected for more serious cases.

Conrad<sup>4</sup> had a maternal mortality of 11.6 per cent. using the bag, and 7.6 per cent. from version. He found the foetal mortality was 50 per cent. by version and 16.3 per cent. with the bag.

There were no maternal deaths in the St. Bartholomew's Hospital series treated by the bag, but the foetus was stillborn in every case.

To sum up, in comparing plugging by the half-breech with the bag, the former has the great advantages that no instrument is required and the pressure on the placental site is continuous and assured, so that further haemorrhage cannot occur. These advantages are not present if the bag is used.

**Traction on the Foetal Head.**  
Willett<sup>5</sup> recently brought forward the ingenious suggestion of exerting pressure upon the placental site by means of traction on the foetal head. He has used for this purpose an instrument which is a modification of the haemostatic scalp forceps employed in cranial surgery. It is passed through the cervix and applied to the scalp where it presents over the internal os, traction being maintained, as in the case of the bag or the half-breech, by means of a weight attached to the handle. He has used it in vertex cases where the os is dilated enough and the placenta does not lie completely over the os. It arrests bleeding while it allows labour to proceed naturally. Dilatation of the cervix is assisted and uterine contractions are stimulated. He finds that it inflicts little damage upon the scalp beyond the formation of a cephalhaematoma. I have no personal experience of its use, but the method

appears to be simple and applicable to those cases in which the cervix is not sufficiently dilated to allow the bringing down of a leg.

## Caesarean Section.

We have now to consider the arrest of haemorrhage and delivery of the patient by emptying the uterus through the abdominal route, so that all vaginal manipulations are avoided. The operation puts an end to the haemorrhage, and at the same time overcomes the risk of further bleeding during the subsequent delivery, which is at once accomplished. In the more difficult cases it gives the best chance to the child and it avoids for the mother any risk of lacerations of the cervix. These arguments, in addition to the ease with which it can be carried out, have led some observers to suggest that slight and suitable cases of placenta praevia should be treated by rupture of the membranes, and others by Caesarean section.

Watson and Miller<sup>6</sup> of Edinburgh, in a statistical analysis of 254 cases of placenta praevia, most of which occurred in the Royal Maternity Hospital, and including several who had come in from a distance in a moribund condition, had a maternal mortality of 25—that is, 9.8 per cent. Of these 25 maternal deaths, 13 were due to ante- and post-partum haemorrhage, 6 to sepsis, and one each to myocarditis, eclampsia, duodenal ulcer, post-partum collapse and mania, embolism, and ante-partum haemorrhage, the last two dying undelivered. The foetal mortality was 64 per cent.

The placenta was central in 81 instances; of these there was a maternal mortality of 22 per cent. and a foetal of 82 per cent. The placenta was partial in the remaining cases, the maternal mortality being 4 per cent. and the foetal 59 per cent. They state that a consideration of the results of the different forms of treatment adopted appears to show that the best results, both for mother and child, are by the two extremes of intervention—that is (a) conservative, with either no rupture of the membranes and plugging, and (b) radical, by Caesarean section. They found it was in patients treated by intermediate methods, such as plugging, together with version or the bag or other methods, that the high mortality occurred. Thus of 61 slight cases treated by conservative methods with the minimum of intervention only one mother died, and that from eclampsia, and the foetal mortality was 41 per cent. Of 14 cases treated by Caesarean section only one mother and one foetus died, giving a mortality rate of 7.1 per cent. in both. On the other hand, of 179 patients treated by the vaginal pack, together with version or the bag or other methods, the maternal mortality was 13 per cent. and the foetal 81 per cent.

This raises the advisability of relegating some of these patients in the intermediate group to the more conservative methods and others to the more radical, leaving a residue of some, upon whom conservative measures have failed, to the intermediate section in the more severe type of cases. In the case of an elderly primigravida with a central placenta praevia it offered the only hope of a living child and entailed less risk to the mother. They consider, therefore, that the scope for Caesarean section might be increased and its wider adoption would tend to diminish the present high mortality rate for both the mother and foetus.

Conrad<sup>4</sup> performs the operation if the child is likely to survive, and gives a maternal mortality of 9.8 per cent. and foetal of 50 per cent. Schweitzer<sup>3</sup> thinks that Caesarean section will be the treatment of the future wherever conditions are good. Gansslo<sup>7</sup> regards it as the ideal treatment provided the child is living and viable and there is no obvious sepsis. He gives a maternal and foetal mortality rate of 6.4 per cent. by Caesarean section, and 8.7 per cent. maternal and 54.3 per cent. foetal when vaginal methods of delivery were employed.

Jellett, in a spirited reply to Watson, points out that the maternal mortality in a series of 264 cases was only 3 per cent. when treated by the vaginal methods of either rupturing the membranes or of pulling down the leg, which figure is far below the results from Caesarean section. He lays special emphasis upon the following points in comparing

the two methods: that the vaginal methods do not include the pack, together with version and the bag, as practised in Watson's statistics, but rupture of the membranes only in slight cases and version in the more severe. He regards the addition of the pack as a grave danger, and considers that no attempt should be made to dilate the cervix by the fingers; that the delivery should not be hastened unless the os is well opened and strong pains are present; and that the patient, once the haemorrhage has been arrested, must be allowed to recover before she is delivered.

We must also bear in mind that Caesarean section for placenta praevia has the special dangers of added shock; of further haemorrhage during the operation, and of sepsis.

In comparing the results from these two methods it is not only the actual method that we must consider but the manner of the subsequent delivery if the vaginal route is employed. Version and pulling down a leg is not of itself attended with much maternal risk, but it will be if the delivery is hurried and is not allowed to occur at a suitable time and to proceed at a slow rate. Caesarean section is obviously unsuitable in patients already suffering from shock and from severe haemorrhage. Here the indication clearly is to arrest the haemorrhage temporarily and to give the patient time to recover. But to deny all place to Caesarean section would be wrong. It is to be advised in the case of an elderly primigravida in good condition who is strongly desirous of a living child, in whom the foetus is alive at or near term, and the placenta covers the os, which is small and rigid. In such a case there is bound to be a considerable amount of inevitable haemorrhage; any vaginal manipulations necessary are certain to cause further haemorrhage, and the outlook for the foetus by the vaginal route is almost hopeless. By doing Caesarean section in such a case as this we can not only secure a living child, but considerably diminish the maternal risk.

#### SUMMARY.

The views which I have put forward and discussed may be summarized as follows:

1. Early diagnosis is essential.
2. Once the diagnosis is made the pregnancy must be terminated.
3. "Slight cases" are best treated by rupture of the membranes and a tight abdominal binder.
4. Plugging is inadvisable, except as a very temporary measure.
5. Certain selected cases may be treated by Caesarean section.
6. Most cases are best treated by external version and plugging by the half-breech. The labour in this case must be conducted slowly.
7. Institutional treatment is necessary in all but the "slight cases."

## TWO CASES OF MIKULICZ'S DISEASE TREATED WITH RADIUM.

BY

A. E. HAYWARD PINCH, F.R.C.S.,

MEDICAL SUPERINTENDENT AND GENERAL DIRECTOR, THE RADIUM INSTITUTE, LONDON.

In 1892 Dr. Johann Mikulicz of Breslau published a paper on a peculiar symmetrical disease of the lacrimal and salivary glands. Four years previously he had shown a case at a medical meeting in Königsberg. In this patient both lacrimal glands and all the salivary glands were converted into tumours in a perfectly symmetrical fashion, thrusting them out of their normal position, and deforming the face. The tumours had arisen gradually, and at the time of examination were dense, painless, and without a

trace of inflammation. The patient exhibited no other sign of disease. The following is an abstract of Dr. Mikulicz's notes of the case.

#### MIKULICZ'S CASE.

January 13th, 1888. The patient was a powerfully built, well nourished man of otherwise healthy appearance. Nothing abnormal was found in the internal organs. No albumin. No enlarged glands found elsewhere. The blood showed no special changes. Pulse and temperature normal. The face was extraordinarily altered in appearance by symmetrical swellings in the neighbourhood of the upper eyelids, and of the parotid and submaxillary glands. The orbital fissures were narrowed to small triangular fissures, the base of which was formed by the inner two-thirds of the edge of the lower lid. A certain amount of convergent strabismus had resulted from this condition.

On palpation a small knobby, dense tumour of transversely oval shape was found under the outer half of each upper eyelid. The conjunctiva itself was slightly reddened and a little thickened. The sight was unaffected. In the parotid area on both sides there was a flattish, not very prominent, and uniform tumour, extending forwards to the middle of the cheek, backwards to the mastoid process, and so lifting the lobule of the ear considerably. In each submaxillary region was a tumour about as long as a hen's egg, of dense consistency, and slightly movable. The two tumours almost met in the middle line under the chin. On opening the patient's mouth the sublingual glands presented as two elongated swellings about the shape and size of an almond set on its edge, and occupying the floor of the mouth on both sides of the frenum linguae. The glands of the soft palate exhibited an enormous increase in size, forming a sharply defined tumour as big as a chestnut on both sides, and being separated by a groove 0.5 cm. wide in the middle line. During the examination of the patient there was a free secretion of saliva, though there was no appearance of a flow.

As the swelling of the eyelids was the only thing which caused the patient much discomfort, a partial removal of the enlarged lacrimal glands was undertaken on February 1st, 1888. On either side a mass of tumour, about 2.5 cm. long by 1.5 cm. broad, was removed. Healing was normal, and the patient left the hospital in a few days, well pleased with the result. The improvement was, however, very transient; the swelling of the upper eyelid speedily recurred, and the patient returned to hospital at the end of March, the swelling of the lacrimal glands being then nearly as large as before the operation. Pilocarpine was injected in the hope that an increased secretion might reduce the size of the glands. No benefit resulted, and on April 19th the right and on May 1st the left lacrimal gland was extirpated. The patient made an excellent recovery, and was discharged ten days later.

He wrote on July 12th, 1888, that he was well pleased with his condition, and that he had no trouble with his eyes. The parotid glands appear to have gone on increasing in size, but they did not bother him. He died of perityphilitis early in August, 1888, after nine days' illness. During his illness the parotids rapidly diminished in size, and at the time of his death were almost normal.

Microscopical examination of the lacrimal glands removed by operation showed that the proper gland parenchyma played a purely passive part, and that the increase in size was due entirely to a voluminous infiltration of the interstitial connective tissue by small round cells (lymphocytes).

Two cases of what appears to be the same disease have been seen recently at the Radium Institute, London.

#### TWO NEW CASES.

##### Case 1.

A married woman, aged 62, was first seen on January 21st, 1924. She was referred to the Radium Institute for treatment by Mr. H. P. Gibb, F.R.C.S. She had consulted him for diplopia which had existed for about eight weeks, and was obviously due to downward displacement of the left eyeball by an enlarged lacrimal gland. No very definite history could be elicited from the patient, but she thought that the swelling beneath the left upper eyelid had begun to be noticeable about nine months previously. She volunteered the statement that she had been in hospital in 1922 for a tumour of the spleen; but no further or more detailed information could be obtained.

The left lacrimal gland, which was the size of an unshelled almond, had displaced the contents of the orbit downwards and inwards, and the orbital fissure was much narrowed; diplopia was very marked. In the right parotid was a swelling the size of a golf ball; it was smooth and elastic, not fixed, and did not implicate the covering skin. In the upper part of the right parotid region was a small scar, indicating the site at which a portion of the growth had been removed for a pathological examination. The pathologist reported "lymphocytic infiltration of the tissues." The left submaxillary gland was swollen to the size of a thrush's egg. The right lacrimal, right submaxillary, and left parotid glands were unaffected. No enlargement of the spleen was appreciable. The blood count was normal. The Wassermann reaction was strongly positive.

The patient received a series of five sittings each of five hours duration on five successive evenings, with applicators containing 120 mg. of radium element, screened with 2 mm. of lead, applied over and around the enlarged glands, so as thoroughly to irradiate them. The last exposure was given on January 25th, 1924.

She was examined again on March 24th, 1924. The swellings in the left lacrimal, left submaxillary, and right parotid glands had completely disappeared. The left orbital fissure was as widely open as the right, and there was no longer any diplopia.

The general principles underlying the following method of preparation are the employment of a culture medium containing blood serum unsterilized by heat, so as to provide a medium as nearly as possible similar to that which obtains in the human body, and the inclusion of part of the filtrate in successive subcultures. It is necessary to emphasize the importance of several factors which are regarded as essential to the preparation of the tuberculin. These are (a) the preparation of a suitable culture medium containing sterile but unheated blood serum of human origin for bacilli of human type and of bovine origin for bacilli of bovine type; (b) the employment of a strain of human and bovine bacilli obtained from an acute or systemic type of the disease; (c) the evolving from this by culturing and subculturing of a strain of tubercle bacilli which will grow actively on the media of human and bovine material before proceeding with the preparation of the tuberculin; and (d) the avoidance in the preparation of the tuberculin of any measures which are likely to interfere seriously with the character of the final filtrate.

The general technique of the method recommended in the preparation of tuberculin of human origin is as follows:

(a) The growth of the special strain of tubercle bacilli on a medium containing unheated blood serum. The morphological, cultural, staining, and pathogenic characters of the bacilli and the toxic and infective properties of the filtrate to be investigated.

(b) A subculture from (a) on a medium comprised of unheated blood serum and an equal portion of the filtrate from (a). A similar line of investigation to be carried out.

(c) A subculture from (b) on a medium comprised of unheated blood serum and an equal portion of the filtrate from (b). A similar line of investigation to be carried out.

(d) A subculture from (c) on a medium comprised of unheated blood serum and an equal portion of the filtrate from (c).

The extent of subculturing will depend upon the growth obtained and the results of the investigations as to the character of the bacilli and the filtrates in the various subcultures. In the method described above the inoculum is taken from each previous culture, but an alternate series of experiments would be necessary in which a fresh inoculum from the original strain on each of the successive series of media is employed. The possibility of stimulating the growth of the bacillus in the various subcultures by oxygen or other means should be considered. The tuberculin, when completed, will consist of two portions: (a) the final filtrate, and (b) the final filtrate combined with an emulsion of bacilli from the final culture. The final filtrate should not be sterilized by heat but by repeated passing through a Chamberland filter, and experimental work would be necessary to prove that it does not possess pathogenic properties. Should experiments prove that in spite of repeated filtration it possesses pathogenic or infective characters, sterilization by some other means, such as by exposure to ultra-violet rays, must be considered. The tubercle bacilli forming the emulsion would require sterilization by heat before the final filtrate is added to constitute (b). The keeping properties of both (a) and (b) should be tested by prolonged incubation.

The aim of the above investigation is twofold. In the first place to obtain and to test a tuberculin composed of reinforced filtrate alone and of the same filtrate in combination with the bacillary contents prepared under conditions as nearly as possible approximating those under which the bacillus grows and develops in the human body. Secondly, to throw some further light on the life-history of the tubercle bacillus and on the character of the toxins elaborated by the organism in the process of growth under natural conditions.

If we attempt to visualize the life-history of the tubercle bacillus in the human body we are forced to accept the following conclusions: (a) That in the process of development and multiplication the bacillus at the outset elaborates exotoxin, and that it grows and matures on a medium of gradually devitalized human tissue and blood lymph which contains exotoxin. (b) That at some period during the life-cycle of the bacillus endotoxins are set free either by a process of extrusion in consequence of interference with the integrity of the fatty envelope or by a destructive process arising from the action of bacteriolytic or autolytic enzymes. The clinical features in the early and more

advanced stages of the disease can only be explained by some such conception with wide variations in the conditions required for the development and completion of the process.

In January, 1924, I submitted an outline of the method described above for the preparation of a tuberculin to Professor Tulloch of St. Andrews University, who kindly arranged for Dr. Cumming, who was working in his bacteriological department, to make a preliminary investigation as to the possibility of preparing a tuberculin by the method suggested. Professor Tulloch thought that before proceeding to investigate the growth on human media—the constituents of which are difficult to obtain—a technique should be elaborated on bovine material. The main results of the preliminary investigation by Dr. Cumming are briefly as follows.

"1. It has been found that even strains of tubercle bacilli which have become accustomed to glycerinated media, both bovine and human, grow reasonably on 1-4 non-heated sterile rabbit plasma with no addition of fresh tissue and no glycerin.

2. A very careful aseptic technique was elaborated for the growth of bovine tubercle bacilli on a cone-shaped island of flesh or heart one inch high and three-quarters of an inch in diameter at the base, in a layer of prepared ox heart extract from one to one and a half centimetres in depth in specially made bottles.

3. In the above and subsequent experiments different dilutions of serums and different diluents (saline, Locke's solution, etc.) were used along with an inoculum of human and bovine strains from human lesions and bovine strains from bovine lesions with practically always perfect results as far as aseptis was concerned, but always with disappointing results as regards growth of the tubercle bacilli.

4. The reasons for these disappointing results appeared to be due to the fact that when these bottles of serum and tissue were incubated autolysis of the tissue took place, with the result that the growth of the tubercle bacilli was thereby inhibited.

5. In one series of experiments growth (of a kind) was obtained in four successive generations, using in each case equal parts of fresh medium and filtrate from the previous batch. In these it was shown that the tubercle bacilli in the fourth generation had not been altered as regards morphology, staining reaction, cultural reactions, or pathogenicity, and that the final filtrate had only very slight antigenic properties, as evidenced by Koch phenomenon.

6. It was further found that the strain of tubercle bacilli employed did not grow so well on fresh human serum sterilized by candlelight as was expected. Dr. Cumming was not able to satisfy himself that this was due entirely to the fact that the strains had been cultivated practically exclusively on glycerinated medium."

In the above summary of the results obtained in the preliminary investigation the one difficulty which at the outset has militated against success has been inability to obtain a vigorous growth of tubercle bacilli on sterile but unheated media of human and bovine material. In one series of experiments with a bovine strain and bovine material a somewhat feeble growth was obtained in four successive generations, using in each case equal parts of fresh medium and filtrate from the previous culture. The fact that such growth was obtained indicates the desirability of further investigation as to the possibility of obtaining a more vigorous growth on successive filtrate media.

The difficulty experienced in obtaining an active growth of tubercle bacilli on fresh human serum is significant and tends to support the thesis submitted in this paper. It emphasizes the necessity of further investigation in the direction of elaborating suitable unheated culture media of both human and bovine material with a view to the evolution of a special strain of tubercle bacilli which will grow vigorously on such media. The question of material of human origin for the preparation of suitable media may present some difficulty, but in the healthy human placenta there is to be found an inexhaustible source of supply.

A further important difficulty met with in the experiments was the inhibition of the growth of the tubercle bacilli in the bovine medium by the occurrence of autolysis of the tissue constituting part of the medium. This was no doubt due to the action of autolytic enzymes in the sterile but unsterilized cone of ox heart in the presence of unheated heart extract or blood serum. Sterilization of this tissue before use as an island for inoculation would prevent autolytic action taking place and would not seriously interfere with the experiment.

Owing to the absence of facilities it has not been found possible to continue this investigation beyond the point

described above. I submit the following proposals for further investigation:

1. The preparation of suitable media of human and bovine material containing unheated blood serum.
2. The evolving of a vigorous strain of tubercle bacilli which will grow on human and bovine media which are not sterilized by heat.
3. The elimination of autolysis in such media and investigation into the possible action of autolytic enzymes on the tubercle bacillus.
4. The preparation of a tuberculin by the method described above.
5. Preliminary investigations to be carried out with bovine tubercle bacilli on media of bovine material.

In conclusion I have to express my thanks to Professor Mulloch for his valuable advice and assistance, and to Dr. Lumming for the time and labour he has given to the preliminary investigation.

## A CASE OF TRANSVERSE ECTOPIA OF THE TESTIS.

BY

A. GRAY BANKS, M.D. GLASG., F.R.C.S. ED.,  
SURGEON, EAST SUFFOLK AND IPSWICH HOSPITAL.

THE interest of the following case is increased by the note in Arthur Keith has been good enough to append.

A man, aged 28, married three years, no children, was admitted to the East Suffolk and Ipswich Hospital in December, 1925, with painful swelling in the left groin. Eighteen years earlier an operation for left inguinal hernia had been performed in the same hospital, but details are unobtainable. He had been aware of the lump ever since the operation and had noticed it becoming gradually larger, more superficial, and moving downwards. Nine months ago he had an attack of acute pain after lifting a heavy weight, and the lump became tender and swollen, and had remained more or less tender since. Two further attacks of pain occurred, one three months, and the other three weeks ago. On each occasion micturition was frequent for about two days; between the attacks there were no urinary symptoms. Sexual power developed when he was about 14, and has been normal since.

He was a spare, vigorous, active-looking man of good intelligence; the secondary sexual characters were well developed. Linear scar of old standing was present over the left inguinal canal, and lying at the external ring just below the pubic spine as a firm ovoid swelling about the size of a walnut, slightly oval and tender on pressure. The scrotum was small and contained only one testis (left), from which an easily palpable cord could be traced upwards. The right side of the scrotum was empty, and no opening could be felt at the usual site of the external ring (the entire absence of any weakness here was affirmed by intra-abdominal palpation during the operation).

### Operation.

An oblique incision was made over the inguinal canal and the swelling identified as a testis (although at first sight the appearance suggested an ovary). It had a well marked tunica vaginalis. On the upper border of the testis a fold of fascia and peritoneum, forming a definite mesorchium and having a cord-like structure with fibrillated end along its free edge, entered the right iliac cavity through the ring and crossed obliquely over the bladder as a lax membrane to the opposite pelvic brim, where it was attached about the point of bifurcation of the iliac artery. The left testis was drawn out of the scrotum and examined. It was rather undersized, devoid of a tunica vaginalis, and on raising the tunica albuginea a normal testicular appearance was seen; the vas deferens of this testis was adherent to, and partially embedded in, a firm structure about a fingerbreadth thick, which ran through the inguinal canal, and descended towards the abdominal part of its in it, the left more out only with great difficulty. When opened it was found to have a cavity admitting a fair-sized probe, the wall about a quarter of an inch thick, and apparently lined with endothelium. The distal part was excised, about one to one and a half inches long to avoid injury to the associated left vas deferens. The ectopic testis was removed with the accompanying fold, the latter having been freed from the above mentioned structure as far as possible, and the oblique muscles and skin sutured. The wound healed by first intention and the patient was perfectly comfortable on discharge two weeks later. A cystoscopic examination was refused.

Serial sections of the ectopic testis, kindly made by Sir Arthur Keith, showed only testicular tubules—no mixture of sex. "No rudimentary ovaries to be found and none in process of formation. The interstitial tissue is normal in amount (A. K.)."

The excessive rarity of the condition is shown by the fact that apparently only four cases of transverse ectopia are recorded.

1. Lenhossék in 1845 first described the condition in a man of 35 with two testes in the left half of the scrotum, the right lying a little higher than the left, in front and medianward. The vasa deferentia were closely united but distinct, the tubes separating only near the prostate.

2. Max Jordan in 1885 reported a case in a child of 8. There were two testes in one patent vaginal process with one vas which divided higher up. The testes were in the left half of the scrotum and the united vasa had coalesced for the greater part of their length.

3. Berg in 1901, operating on a congenital left inguinal hernia in a boy of 13, found two testes—one normal in a well developed scrotum, and the other, almond size, at the left ring. Both cords were intimately connected with the hernial sac; the ectopic cord had a distinct mesentery and passed up across the space of Retzius to the right inguinal region, whence it descended to the pelvis. The right ring was palpated and found closed.

4. Halstead (1907) records a case with two small testes and a large left inguinal hernia; the epididymes were fused, but the vasa deferentia were distinct up to the region of the internal ring where they were united.

### NOTE BY SIR A. KEITH.

The abnormal structure found passing upwards from the testis, and descending to the base of the bladder, can only be the result of fusion and persistence of the Müllerian ducts, forming a uterus masculinus of unusual size and persistence. If this were drawn down into the hernial sac, as is quite possible, it would bring with it the attached undescended right testis. The vasa deferentia should be embedded in the "structure," exactly as found at operation. This, I think, is the true interpretation, not a double or dichotomous condition of the left testis.

It is to be supposed, therefore, that in this patient there had been a persistence of the stage reached and usually passed through in the third month of development.

## NEPHRO-URETERAL ANASTOMOSIS AFTER COMPLETE AVULSION OF THE URETER.

BY

R. CAMPBELL BEGG, M.C., M.D., F.R.C.S. ED.,  
M.Sc.N.Z.,  
GENITO-URINARY SURGEON, WELLINGTON HOSPITAL, N.Z.

A MAN, aged 42, was referred to me on January 19th, 1926, complaining of constant pain in the right loin. It had existed with varying intensity for many years, but he had had nothing in the nature of an attack of renal colic. Investigation showed that there was a round calculus in the right renal pelvis, and that the urine was infected with *B. coli* and was delivering pus. The kidney function, however, by dyo tests showed that there was only slight loss of function on the right side as compared with the left. In the latter, indigo carmine, after intravenous injection, appeared in strong concentration in five minutes, while the dyo did not appear till six and a half minutes from the right side, but the concentration was good. The calculus appeared to be about 1 cm. in diameter, so pyelo-lithotomy was advised.

### Operation.

On February 12th the kidney was exposed with some difficulty owing to its high position; a portion of the twelfth rib had to be resected. The organ seemed healthy except for one or two points of subcapsular scarring. The pelvis was mostly intrarenal and the calculus was lying just outside the hilum, while immediately below it a ureter of normal calibre passed downwards. The calculus was removed by a vertical incision. The walls of the pelvis seemed to be very thin and there was a ring of ulceration where the stone had been lying. An attempt to stitch the walls of the incision with the finest round needle and catgut resulted in every stitch pulling through. My assistant had to exercise a certain amount of tension on the kidney to keep the field in view, and suddenly the ureter came completely away from the pelvis at the line of the circular ulcer. The line of separation was very close to the kidney, and the little pelvic tissue available for anastomosis was so friable that an end-to-end junction was impossible; after some attempts at this there remained no extrarenal pelvis, but merely a few bits of ragged tissue around the orifice of the renal sinus. Nephrectomy was considered, but owing to the comparatively good renal function present seemed undesirable. The ureter was not dilated and had good muscular walls. A No. 6F catheter

was passed butt-end first down the ureter into the bladder and the other end into the upper major calyx. The upper end of the ureter was split for half an inch on its outer surface and by means of stitches carried from it through the intrarenal pelvis and out through the kidney substance, so that the margins of the tube were approximated roughly to the frayed walls of the pelvis. A capsular flap was turned down to cover the junction. To ensure adequate drainage the pelvis was opened from the cortex and a drainage tube tied in. The free end of the catheter in the bladder was recovered and pulled through the urethra by means of flexible forceps through an operating cystoscope. The catheter was allowed to remain in place for seven days and the urine drained through the nephrotomy wound. At the end of that time there was spasm of the ureter on the right side and the ureteral catheter was removed.

Urine began to pass down the affected ureter, as evidenced by blood in the urine and a marked diminution in the leakage from the loin. On the tenth day a catheter was passed up the right ureter and met with no obstruction. Oxycyanide was injected through the catheter and out through the loin. In six weeks the wound in the loin was healed and all the urine was passing through the normal channel. Cystoscopy showed that the effluxes were normal, and a large ureteric catheter passed into the pelvis of the kidney without obstruction. The pelvis could be distended to 10 c.cm. and then caused discomfort. Indigo carmine given intravenously appeared from the left side in strong stream in three minutes and from the right in only moderate concentration in seven minutes. The calculus was of oxalate type, almost exactly spherical, and 9 mm. in diameter.

At the date of writing (June 3rd) the patient states that he has no trouble and is carrying on his work, but that he had one attack of renal colic after returning home.

In cases where the kidney is high the proper exposure of the ureter and pelvis for operations on the pelvis may require a good deal of tension to pull the kidney forward and expose the posterior aspect of the pelvis. This can be obviated to some extent by carrying the lower part of the incision almost horizontally inwards instead of obliquely downwards and inwards. Such a catastrophe as occurred in the case reported, however, is unlikely to occur except where the pelvis is extensively ulcerated and its walls thinned. The question arises as to whether the incision should be made down to the calculus through the extra-pelvic fat without dissecting this away, so as to display the wall of the pelvis. It has been claimed that this technique gives quicker healing and is less likely to leave a urinary fistula. My own experience has been, however, that the quickest results are obtained by exposing the pelvic wall, and after careful suturing bringing a fat or capsular flap across, though it is probable that where any difficulty is experienced in sewing owing to the friable nature of the tissues the wound closes without any suturing at all if attention is paid to dilating the ureteral canal at the time of the operation and afterwards. To be forced, owing to an operative mishap, to remove a sound though slightly infected kidney in a case of stone is a disaster of the first magnitude, owing to the possibility of subsequent formation of calculus on the other side. An improvement in technique in this case would have been to pass the upper end of the splint catheter through the nephrotomy wound so as to give perfect control of both ends and prevent the possibility of the instrument coming out too soon.

## ECZEMA AND DENTAL DISEASE.

BY

A. ANNESLEY GOMES, F.R.C.S.I., D.P.H.,  
L.D.S.R.C.S. Eng.,  
BURNLEY, LANCAIRE.

THEORIES of the etiology of eczema may be stated briefly as: (1) neurotic, (2) local irritation, (3) thyroid deficiency, (4) toxic. The last is perhaps the most popular. The toxins occur in connexion with (a) constitutional diseases—for example, gout, diabetes; (b) chronic Bright's disease; (c) certain diseases of the liver; (d) alimentary tract. While mentioning the alimentary tract most writers limit the suggestion to the gastro-intestinal portion of it, for imperfect metabolism and malassimilation are thought to be the cause. The importance of the oral part seems to be little recognized. Macleod admits that digestive derangements may aggravate the disease, but says there is no evidence that they cause it *de novo*. French writers, he says, consider eczema a cutaneous manifestation of a diathesis not yet defined, and Brocq calls it "eczematiza-

tion," the symptom, rather than eczema, the disease. Given a diathesis or predisposition, the toxins arising from certain dental diseases can cause the manifestation of eczema or aggravate it if it already exists. The dental poisons may be absorbed in two ways: (1) by swallowing the pyorrhoal or other septic discharges from diseased dental tissues; (2) by direct passage into the general circulation of toxins from septic foci concealed in the bone related to the teeth. The immediate recovery from an illness previously protracted, which I report here, proves this conclusively.

A man, aged 44 at the time, had recurrent attacks of eczema, beginning at about the age of 37. The last attack was of eighteen months' duration. It was intractable and increasing in severity. After persistent treatment by his family doctor and the consultant there was, according to the patient, only a slight improvement. His doctor now began to suspect oral sepsis. When I first saw the patient the eruption extended literally from head to foot in all its forms: redness, vesication, exudation, and crusts variously distributed. Examination of the mouth revealed general periodontal disease. There were pyorrhoea and secondary changes in the alveoli with chronically inflamed gums over them. I made a clearance of all the teeth (twenty) under regional anaesthesia (superior maxillary and mandibular) with novocain E. The after-effects of the injections were remarkably mild—only a slight soreness at their seats. The eruption began to disappear almost immediately. Within a week there was marked improvement, and in a fortnight the patient was able to discard the dressings of his head, hands, and feet, and walk down to my surgery for his temporary denture. After another fortnight he was quite cured and strong enough to attend to his ordinary duties, the only trace left being a roughness of the skin.

This case was treated in June, 1923, and I deferred reporting the results to give time for observation. Since then he has had a few short and mild attacks, which are directly attributable to his own indiscretions. These later attacks support the suggestion of a diathesis, but the immediate recovery following the extraction of the teeth shows that dental disease can be a serious contributor factor to be reckoned with.

## British Medical Association.

### PROCEEDINGS OF SECTIONS AT THE ANNUAL MEETING, NOTTINGHAM, 1926.

#### SECTION OF PATHOLOGY AND BACTERIOLOGY.

Professor J. SHOLTO C. DOUGLAS, M.D., President.

#### DISCUSSION ON LEUKAEMIA AND ALLIED CONDITIONS.

##### OPENING PAPERS.

I.—G. LOVELL GULLAND, C.M.G., M.D., F.R.C.P. Ed.  
Professor of Medicine and Clinical Medicine in the University of Edinburgh; Senior Physician to the Royal Infirmary, Edinburgh.

At first sight it might seem impossible to say anything new about leukaemia, but the views of the profession evidently want clarifying as to the nature of the disease. The current textbooks of medicine and pathology are by no means dogmatic and some of them even evade any definite statement as to cause and nature. The original picturesque idea that it is a suppurative of the blood has, of course long ago disappeared, as well as that of a mixed leucocytosis. More recently came attempts to find parasites in the leucocytes, which also came to nothing, and for a long time back the view that the disease is neoplastic has steadily gained ground, though some workers adhere to the notion that it is caused by organisms. The acute leukaemias certainly often enough resemble clinically an acute infection, and if fowl leukaemia is really the same disease the fact that it can be transmitted from one bird to another by the filtered cell-free juice of leukaemic organs is a strong point. But I do not think that we should be led away by a single fact, which after all may be capable of some other explanation, to neglect the great body of evidence which certainly points away from cause

## LEUKAEMIA AND ALLIED CONDITIONS.

tion by a filter-passer and towards the neoplastic theory. A single filter-passer would not meet the case; there must be several, each capable of causing the proliferation of different varieties of leucocytes, and of such difference in virulence as to cause the death of the patient at periods varying from a week or two to ten years or more. For it must be remembered that leukaemia is always fatal in the long run, which cannot be said of any organismal disease with the same certainty. We have elaborated this argument fully elsewhere,<sup>1</sup> but I realize that the last word has not yet been said.

I hold the view that leukaemia is a sarcomatosis of the leucocytes, and that tumours would be formed by them more often than is actually the case were it not for the mobility of the cells and their non-cohesiveness—the fact that they permeate all fluids and tissues without forming a being a tissue in the proper sense. In leukaemia accidental tumours are formed in the skin, in the glands, in bone, and so on, as everyone knows; but the marrow, in the disease is the proliferation in the blood, organs, and metastatic overflow thence into the marrow, and the lymph glands, and so on—and encourages it to proliferate for its own purposes, forms traps to hold it—marrow, there, but it is always eager to be off on its own business.

It is true that to call leukaemia a neoplasm is merely to explain the known by the unknown. We know next to nothing of the causes of tumour growth, and none, either of the modern theories or of the older ones of irritation, seems to be specially applicable to this disease. It seems always to start *de novo*. But it is equally true that while we know a good deal about the behaviour of leucocytes in disease, especially about their response to organismal influences, we know very little about their behaviour in health. In particular we do not know what influences maintain their numbers and proportions in the blood at so constant a level—so constant that a variation in number of a couple of thousand per cubic millimetre or an alteration of 10 in percentage at once sets us looking out for some pathological condition.

We are tempted to think of endocrine influence, but there is little to support this. The absolute or relative lymphocytosis which occurs in some cases of Graves's disease is almost the only more or less constant alteration that occurs in any form of endocrine disturbance that is known to us. It is open to anyone to maintain that the pineal, carotid, or coecygeal gland regulates leucocyte number.

Food certainly has some influence, probably both through the amount taken and variations in the kind of food, and one may assume that poisons present in the blood on their way to excretion or destruction must have some effect. These poisons may be metabolic or absorbed from bacteria present in the hollow viscera. But if these are the only factors—they are the only obvious ones—it is curious that they should be so well balanced. There is probably some other regulating factor, and it is possibly disturbance of this which is responsible for leukaemia.

Leukaemias may be classified according as one looks at them from the cells found in excess in the blood, the clinical standpoint or the pathological. Clinically from the cells found in excess in the blood, the acute forms may be myeloblastic, lymphocytic, or myelocytic; and myelocytic or promyelocytic; the really different—and myelocytic or promyelocytic; the chronic forms myelocytic and lymphocytic or lymphatic. The chloromas, as far as the blood is concerned, fall into one or other of these classes.

We have adopted the classification into granular and non-granular types as follows:

Non-granular:  
Myeloblastic (acute).  
Lymphatic (acute or chronic).

Granular (acute or chronic):  
Mixed.  
Chloroma.

This classification, however, like any other, is merely a matter of convenience, and expresses a personal view. It is hard to get rid of such old terms as spleno-medullary, and acute lymphatic as applied to the myeloblastic form. Much more important than classification is it to try to understand what lies behind the different forms—why some are acute and others chronic in their course, why

some show a million leucocytes per cubic millimetre and others a few thousands. To follow this we must briefly consider the phylogeny of the leucocytes and their relations to one another. The most primitive form is the myeloblast or lymphoidocyte, which remains throughout life in certain numbers in the bone marrow, though it probably does not take any active part in the production of the different series except in pathological conditions. The four series develop in much the same way. The mother cell of each is a leucocyte with large rounded nucleus and relatively small amount of cytoplasm. In the lymphocyte series this is known as the large lymphocyte, which again becomes a monocyte, and which may further develop into the large mononuclear or hyaline cells, and the transitional, which last are the "ripe" form. In the three "granular" series there is this difference from the lymphocyte series—that a promyelocyte form with scanty granules is inserted between the myeloblast and the myelocyte, which latter is the functional equivalent of the large lymphocyte from the reproductive point of view in normal conditions. It is in these cells that mitosis is most frequently seen in the marrow. The rounded nucleus of the myelocytes in those destined to develop further becomes kidney-shaped and astropheres, or rather of the radii passing from them, and ultimately the "ripe" polymorphonuclear form is produced in each series. It is this form alone which is really adapted to rapid amoeboid movement, though it occurs in all the forms to a greater or less extent. It is to a certain extent a misnomer to speak of the lymphocytes as non-granular, as all the forms contain azurophil granules. The term "non-granular" is a legacy from the triacid stain and the eosin-methylene-blue mixtures of early days, but it has remained, as it is practically convenient.

The leukaemic process may affect this development at almost any point and in any series. But there is this striking peculiarity—that in the chronic granular forms all the series are affected, though not usually to the same extent. That is to say, all the cells normally present in the marrow—myeloblasts and lymphocytes—appear in ripe and unripe cells of all the forms in the marrow. Most commonly the neutrophil series preponderates, but a great proliferation of all the forms in the marrow. The proportions differ greatly in different cases, and even in the same case from time to time, even from day to day. It is difficult to explain why this should be so. If the variations occurred only in early cases one might conclude that they represented the involvement of fresh areas in the marrow by the various types of cell; but they occur also in fully developed cases, which have been going on for years, and in which probably the whole marrow has long been affected. It is difficult also to understand why myeloblasts and lymphocytes should increase. Is it a result of the same stimulus, or is it a reactive phenomenon, like the formation of the stroma and the fresh blood vessels in true tumours?

The acute granular forms are so rare that it is difficult to generalize about them, but they are probably in most cases promyelocytic rather than myelocytic. They also drag in myeloblasts. One must be careful, however, not to attach too much importance to the occurrence of a few myeloblasts in the circulating blood. They appear in any condition in which there is profound marrow disturbance, in pneumonia and other conditions causing leucocytosis, in pernicious anaemia, and even in severe secondary anaemias. It is difficult to say whether they appear in these conditions in response to chemiotactic influence, or as the result of mechanical disturbance.

The chronic non-granular form, or chronic lymphatic leukaemia, is unfortunately rare, for it is in some ways the most interesting variety and deserves very full study. It may be extremely chronic. I have seen at least three cases in which the enlargement of glands had lasted for ten years or more, though the blood had not been examined. Others show little enlargement of glands, but have large spleens, and in them also the blood, when they come under

observation, shows such a high leucocyte count that the disease must certainly have been present for a long time. During this latent period there seems to be less disturbance of general health even than in the chronic granular cases, and until the final breakdown occurs there is less anaemia and less tendency to the recurrent haemorrhages which may be so marked a feature of the chronic granular form. I am satisfied that many of the cases which are described as acute lymphatic leukaemias with high white counts are really the terminal stages of the chronic form. The striking feature of the blood in the chronic cases is the high proportion of lymphocytes, usually small, and sometimes reaching the high figure of 95 per cent, or even higher. Another feature is the fact that a large number of the cells are obviously dead or degenerated, and consist only of smeared nuclei in films—the thinner the films the more smeared nuclei. This degeneration of cells is far more common in all the non-granular forms, acute and chronic, than in the granular varieties, in which it is not nearly so obvious.

I am becoming somewhat sceptical of the existence of a really acute lymphocytic form. Most of the descriptions date back to a time before the myeloblast was recognized as a separate entity, and are based on staining which did not bring out the difference between lymphocyte and myeloblast, and I personally have not seen any case of late years which I could confidently call acute lymphatic, as distinguished from myeloblastic, leukaemia. As I have already said, many of the cases so described are really the terminal stage of the chronic lymphatic form. Probably most, if not all, as I am inclined to think, of the acute non-granular cases are really myeloblastic. But it is to be remembered that in many of the myeloblastic cases there is a lymphocyte overgrowth also. This is always most evident early in the case; the total white count may not be greatly raised, but there is a high proportion of non-granular cells—85 or 90 per cent.—of which 25 to 50 per cent. may be myeloblasts, the rest lymphocytes. As the case advances the proportion of myeloblasts steadily increases, until at last, if the case lasts long enough, practically all the cells are myeloblasts. Of course, a large haemorrhage or other accident may prevent the completion of the picture. This seems capable of two explanations—either that at first the myeloblasts continue to be capable of developing into lymphocytes, and later cease to be capable of doing so, or that the primary lymphocyte increase is reactive in the same way as that in the chronic granular type. I am not prepared to say that this happens in every case of myeloblastaemia. Certainly in many of them the myeloblast picture is fully developed from the first, but of course the first blood examination is not always made at the beginning of the disease.

I need say nothing about the "mixed" forms, for it will be evident from the foregoing that almost every case is "mixed" at some stage. Even in the chronic non-granular cases, which are more true to type than any of the others, some myelocytes and myeloblasts will appear towards the end of the case, for reasons which will be evident when I come to speak of the red cells.

It is a truism that leukaemic patients do not die because of the leucocyte excess, except in so far as the heaping up of cells in important organs, such as the liver and kidney, interferes with their function, or thrombi of leucocytes predispose to haemorrhage. They die most often of the accompanying anaemia and its results, of haemorrhage, or of intercurrent conditions. How is the anaemia produced? Why is it that the chronic forms will go on for years with only a slight secondary anaemia or none at all, while the acute forms may drop a million every few days and terminate with a count of perhaps a million, a high colour index, and megaloblasts in the circulating blood?

I feel sure that the answer to these questions lies in the rate at which the marrow is filled up by the proliferating leucocytes, so that it ceases to be an erythroblastic tissue to a great extent and becomes wholly or almost wholly a leucoblastic tissue. There is no other organ in the body, except perhaps the spleen, which has the same potentialities of expansion as the marrow, and we all know how this power of expansion is utilized in the diseases which produce leucocytosis and in the primary and secondary anaemias. In the

majority of leukaemias the primary change is in the marrow. We do not know, and possibly we shall never know, whether the change begins locally or generally; nor does it greatly matter, for the mobile altered leucocytes, when they pass into the blood stream, must be carried to all parts of the marrow as they are to all other organs, and start proliferation in fresh places. There must of course also, in addition to this, be the steady overgrowth and filling up of the fatty marrow in the long bones from the active foci at their ends. If this filling up of the whole available marrow space proceeds slowly, there is time for the erythroblasts which are crowded out of their normal habitat to spread themselves also into the newly activated parts of the marrow and to keep up the supply of red corpuscles to the blood. They probably do this at some disadvantage, for even in the earliest chronic leukaemias the colour index is usually lowered though the red count may be normal or nearly normal, but the process is a slow one, and patients adapt themselves to a lowered haemoglobin percentage in an astonishing way, not only in this, but in all chronic anaemias. In the chronic granular type normoblasts escape or are extruded in large numbers into the blood; and there is evidence that they proliferate there, and even also in the liver and spleen to which they are carried, thus recalling the blood formation of foetal life to a certain extent.

In the non-granular chronic cases normoblasts do not escape into the blood in the same way. In a myelocythaemia it is often difficult to find a single field without one or more normoblasts; in a chronic lymphocythaemia it is often difficult to find any. The reason for this is probably complex. We must remember that lymphocytes are not true marrow cells in the same sense that myelocytes are. They occur everywhere in connective tissue throughout the body—massed in lymph glands and adenoid tissue, scattered in ordinary fibrous tissues, and are found in the marrow quite as much because it is a connective tissue as because it is a blood-forming organ. I am inclined to think also that very many at least of the lymphocytes in the marrow lie in connective tissue spaces rather than in blood spaces, so that their relation to the erythroblasts is not as close as that of the granular cells. There is no reason to suppose that the leukaemic process may not start in any part of the lymphatic apparatus. If it begins in lymph glands or in the adenoid tissue of the hollow viscera which drains into lymph glands, it may remain localized for a long period, and there may be no influx of lymphocytes into the blood. Sooner or later the process will spread to the marrow, but even when it reaches it the reproduction of lymphocytes is slower than that of myelocytes, and possibly it occurs more in the connective tissue spaces. The result will be that there is more time for erythroblastic proliferation, so that the erythrocyte equilibrium is more easily maintained. With both the chronic types a point is reached at last when red corpuscle formation is seriously interfered with, a rapidly advancing anaemia occurs, and leads to death by haemorrhage or in other ways, just as in the acute forms. In the chronic forms one can sometimes restore the balance again by destroying the leucocytes by radiation or in other ways, and so give the erythroblasts a fresh chance, and the patient a fresh start. In the acute forms we have not yet succeeded in doing this.

In discussing the anaemia of the acute forms we need only consider the myeloblastic variety—the myelocytic or promyelocytic form acts in exactly the same way. Myeloblasts occur only in the bone marrow; when they are attacked by the leukaemic process they evidently proliferate with tremendous rapidity, and rapidly fill up the marrow spaces, leaving no room for not only the erythroblasts but even the myelocytes. I have sometimes found the marrow in these cases, in places at any rate, pure white to the naked eye, and have found practically nothing but myeloblasts in films from these bits of tissue. As a result normoblasts are found in the blood early, though never to the same extent as in some of the chronic granular cases, because regeneration is so profoundly interfered with in the marrow. Often, indeed, this interference is carried so far that the normoblastic function passes more or less into abeyance and the megaloblasts are called upon, so that

OCT. 27 1916]

# LEUKAEMIA AND ALLIED CONDITIONS.

the colour index, which is always below unity at first, ultimately becomes high, megaloblasts appear in the blood, and as far as the red side is concerned, the picture of pernicious anaemia is produced with more or less fidelity. The same thing may occur in the terminal stages of the chronic forms, though not so constantly, and it is apparently more common in chronic leukaemias in children, in whom the regression to the megaloblastic type of blood formation is always easy. In all the forms haemorrhage, when it occurs, increases the anaemia much more than it would in a normal person, and is always badly borne outmost and there is no reserve.

The ordinary variations in the white count in leukaemia are easy to understand. The 500,000 of the chronic granular, 100,000 to 200,000 of the chronic non-granular, are due to the complete filling of the marrow, with constant reproduction, and very probably to reinforcement from the cells lodged in the liver and spleen, and perhaps those in the blood itself. The acute cases never show such high counts—the more acute the case the lower the count. Probably this is because the newly formed cells in the first instance remain in the marrow and gradually fill up all the space, and it is only when that process is completed that the excess appears in the blood, though the proportions are altered from the first.

But in the chronic cases of both types, especially the granular, the count may drop to normal, or near it, either as the result of such an intercurrent affection as influenza or without any apparent cause. One can understand this in the case of influenza or chronic tuberculosis, which are both diseases of negative chemotaxis, but the causeless remissions are so far unexplained. They may be related to the occasional remissions that one sees in the growth of true tumours.

There are other problems, such as the fever which always occurs in the acute cases, and often in the chronic, with which time will not let me deal, but which will I hope, be discussed by others.

The subject of our debate is to be "leukaemia and allied conditions." As I see it, there are no conditions which are allied to leukaemia in the strict sense; myeloma is the nearest relation, and from the clinician's point of view it does not give rise to difficulty in diagnosis, as the blood is not leukaemic. Chloroma is a true leukaemia, and presents no difficulty in diagnosis, provided that the blood is examined, and that there are tumours visible or palpable, especially if the green colour can be distinguished through the skin. It is perhaps worth noting that I have seen two cases of hypernephroma with orbital metastases producing proptosis which suggested chloroma. In these cases, however, there was a leucocytosis, and not a leukaemia. A year ago I published a paper in the *Journal of this Association* on "Difficulties in the diagnosis of leukaemia," and I do not propose to go into that subject fully now.

The only general diseases which are likely to give rise to real difficulty in diagnosis are whooping-cough and glandular fever. The former may show a high leucocytosis with a high percentage of lymphocytes, and I have seen reports of cases in which what was obviously whooping-cough with a catarrhal pneumonia was described as acute lymphatic leukaemia. I am not aware that any proper study of the bone marrow in fatal cases of whooping-cough has been made. Glandular fever, when it occurs sporadically, may give rise to real difficulty: when it occurs as a school epidemic it is not likely to give trouble. There is apparently one form in which the leucocytosis increase is polymorphonuclear neutrophil; I have seen only one case of this. In the majority there is a true lymphocytosis, sometimes with high count and high lymphocyte percentage, and the enlargement of glands and of spleen, with the fever, make it possible to imagine a leukaemia. But in acute leukaemias the glands do not enlarge so rapidly, there is more rapid and severe anaemia; and, further, I have never seen a myeloblast in the blood of any of these cases. They sometimes give rise to anxiety later for the blood change may take weeks or months to disappear, but it will always return to normal in the

long run. The patients may be very ill, but I have never seen or heard of a death, so that the marrow has probably never been investigated.

The splenic anaemia of infants is a condition which is now so well recognized that it is not likely to be confused with the true leukaemias, though I have seen cases in which the diagnosis was for some time in doubt. Indeed, the blood in children, because of its high lymphocyte percentage and its tendency to revert to megaloblastic formation in any severe anaemia, is constantly giving rise to difficulty.

But I find that my own greatest difficulty with aberrant leukaemias is their aleukaemic stage, of the type which has been described as leukaemia. It happens that I have two cases of the kind under observation at the moment, and I may describe them briefly.

The first was a man who had been getting pale and out of health for a couple of years, but had never gone to a doctor. The spleen came 1½ in. below the umbilicus and 1 in. to the right of the middle line, the liver 1½ in. below the rib margin. The blood count was: red cells 1,780,000 per c.mm., haemoglobin 43 per cent., colour index 1.2, white cells 1,200 per c.mm.; a fair number of megaloblasts, and no abnormal cells among the leucocytes. This was, of course, a typical picture of pernicious anaemia. With an unusually large spleen, and probably liver also. A second count a month later was: red cells 2,610,000, haemoglobin 50 per cent., colour index just below 1, white cells 2,800, very few megaloblasts, no abnormal leucocytes. The spleen was a little smaller, especially in the transverse direction. Two months later the liver extended to the umbilicus, the spleen 2 in. below it; red cells 1,950,000, haemoglobin 35 per cent., colour index just below 1, more megaloblasts; white cells 4,000—of these at least half were abnormal cells, the majority myelocytes, the remainder myeloblasts.

The second case came to me with a history from a very competent observer. He also had been pale and out of health for some years, but had only recently come under observation. The spleen came to the umbilicus, the liver was 1½ in. down. Some time before I saw him the count was: red cells 4,000,000 per c.mm., haemoglobin 70 per cent., white cells 15,500, of which about 25 per cent. were myelocytes and myeloblasts, fairly numerous nucleated red cells. My own count was: red cells 3,170,000, haemoglobin 68 per cent., colour index just over 1, white cells 4,800, fairly numerous megaloblasts, no definite myelocytes, but some myeloblasts. I made the note that I had never seen a pernicious anaemia, which the blood indicated pretty definitely, with so large a spleen, the white cells rose again for a short time to 13,000, then fell to 5,000, and the myelocytes reappeared; the red count remained at the same figure as my own. My count two months after the first one was: red cells 3,043,000, haemoglobin 48 per cent., colour index 0.8, white cells 5,000; only 1 nucleated red, a normoblast, was seen; about 20 per cent. of the leucocytes were abnormal, about equally myelocytes and myeloblasts; the liver and spleen were both distinctly larger than before, although the patient's general condition had improved.

Now are these cases, and such as these, aberrant pernicious anaemias or aberrant leukaemias? I am inclined to think that both, especially the latter, are leukaemias. Time will very likely clear up the difficulty. It is always easy for the pathologist to say, "*Respicere finem*," but the unfortunate clinician has to make up his mind as to diagnosis and treatment on the evidence he can get at the time. We look for your sympathy, and in all our difficulties we do our best to avoid giving you an opportunity for making a final diagnosis.

II.—S. W. PATERSON, M.D., D.Sc., M.R.C.P.,  
Physician, Ruthin Castle, North Wales.

THE present communication consists of an analysis of a series of cases of diseases of the blood-forming organs. Most of the material was obtained in the pathological department of the Melbourne Hospital; some privately observed cases have been added.

## CLASSIFICATION.

Until more is known of the etiology of diseases of the blood-forming organs, no satisfactory classification from the point of view of causation can be offered. A pathological classification may be made according to the type of normal or abnormal cells predominating in the lesion.

Such a one, modified from that of Grüner, has been found useful in teaching and is given below.

#### Disorders of Reticulo-endothelial System.

1. Hyperplasia of normal cell elements:
  - (a) Lymphocytes. Lymphatic leukaemia, lympho-sarcoma.
  - (b) Early leucocytes. Spleno-medullary leukaemia.
  - (c) Reticulum. Hodgkin's disease; Gaucher's disease.
  - (d) Fibrous tissue. Passive congestion, syphilis, malaria.
2. Alteration of metabolism of normal cells. Chloroma.
3. New cells produced. Myeloma.
4. Excessive formation of stroma with dystrophy of specific tissue cells:
  - (a) Return of foetal blood cells, megaloblasts. Severe anaemia.
  - (b) Fragility of red blood corpuscles. Familial haemolytic spleno-megaly.
  - (c) Increased destruction of red corpuscles. Splenic anaemia.
  - (d) Relative leucocytopaenia. In glandular fever, intravenous injection of foreign protein.

#### CLINICAL GROUPING.

A more useful classification in practice is according to the predominant clinical sign, and I propose to analyse my cases in this way. The method, however, involves a certain amount of repetition. Taking tumour of glands, tumour of spleen, and mediastinal tumour as the most striking features on clinical examination, the cases fall into the following groups.

##### 1.—Primary Enlargement of Lymph Glands.

By primary enlargement of lymph glands is meant tumour of lymph glands where known causes, such as syphilis, tubercle, or glandular enlargement secondary to neoplasm or pyogenic infection, are excluded.

(a) *Acute Primary Glandular Enlargement with Leukaemia (Acute Leukaemia).*—There were 12 cases in this group—1 female and 11 males. All ages were affected, and there were five patients over 55 years of age; the younger cases, however, showed a more rapid evolution. The symptoms were severe, with fever, loss of weight, and haemorrhages from mucous membranes and into the skin; enlargement of the lymph glands throughout the body and enlargement of the spleen occurred in most cases. The white corpuscles were always increased, often to a great extent, counts of many thousands to three-quarters of a million per cubic millimetre being met with. There was progressive secondary anaemia. The course was rapidly downhill, and invariably a fatal termination took place in a few weeks. The white cells found may be either lymphocytes or of myeloid origin (myeloblasts). From the clinical standpoint the differentiation is not of much importance, as these cases are fatal whatever the treatment.

(b) *Acute Primary Glandular Enlargement without Leukaemia (Glandular Fever).*—This occurs mostly in young people, the symptoms being malaise, fever, and a general enlargement of lymph glands in the neck, axillae, and groins. There is often sore throat, with a pseudo-diphtheritic membrane, and Vincent's bacilli and spirilla are found. The white blood cells are usually increased, and there is a relative lymphocytosis. The cells are normal in character; the symptoms are not severe, death being rare; there are no haemorrhages, and the prostration and anaemia of acute leukaemia do not occur. But the diagnosis from an early acute leukaemia may be difficult and give rise to great anxiety at the beginning.

(c) *General Glandular Enlargement without Leukaemia (Hodgkin's Disease).*—This group of 31 cases in my series showed a characteristic histological picture in the affected glands, which is typical of Hodgkin's disease. Males were affected more than twice as frequently as females. The age at onset varied from 11 to 69 years; in 10 the disease began before the age of 30, and in 4 after the age of 50; 17 first showed symptoms between the ages of 30 and 50, and of these 9 (30 per cent.) were between 30 and 40. The course of the disease was progressive in half the cases (16), relapsing in 7, and acute in 1, while 7 were diagnosed in the early stages on histological evidence. In 13 cases known

to have died the duration of the disease was four months to four years, with an average of two years. The symptoms were malaise and weakness, loss of weight, often night sweats; no haemorrhages occurred; cough was frequently noted, and hydrothorax supervened in 4 cases. The glands first affected were the cervical group of one or other side in 19 (60 per cent.). Later, the glands of the other side of the neck enlarged, then the axillary and inguinal groups. The mediastinal glands were affected in 9 (29 per cent.), and the mesenteric glands enlarged in 3 (10 per cent.). The liver was noted as increased in size in 3 cases. The spleen was greatly enlarged in 4, and palpable in 6 others. The blood usually showed a secondary type of anaemia; the red cell count may be as low as 1,500,000 per c.mm., with a corresponding reduction of the percentage of haemoglobin. The white cell count varied from 2,000 to 28,000 per c.mm., with an average of 10,000. Eosinophilia was noted in several cases. Abnormal types of cells are not present in the blood. The glands are usually painlessly enlarged, discrete, and not attached to the skin or fascia, and they may attain a large size. Microscopic examination of an excised gland gives a typical picture of hyperplasia of the reticulo-endothelial cells, agglomerations of multinucleated giant cells, and as well in the early stages, an increased number of eosinophilic cells. In the later stages degeneration of the cells takes place, and there may be increase of fibrous tissue and scarring. There has been much discussion as to the relation of Hodgkin's disease to tubercle in a more or less modified form, but generally it is allowed that the frequent association here, in Europe, and in America, is due to secondary accidental infection. Certainly it is rare in Australia, where tubercle is, less common, to find the two conditions together. The course of Hodgkin's disease seems to be more or less rapidly fatal. Healing has been reported as the result of various procedures, but the experience of these hospital cases is depressing. Retrogression seems to be obtained by arsenic internally or treatment with x rays and radium, but relapse occurs, and the patient tends to go downhill more or less quickly.

##### 2. Chronic Enlargement of the Spleen.

Chronic tumour of the spleen may be associated with malaria or hepatic portal cirrhosis, or may be caused by hydatid cyst in Australia. Enlarged spleen frequently accompanies Hodgkin's disease (one-third of the cases in the series quoted); the enlarged lymph glands associated with splenic tumour would assist the diagnosis, and microscopic section of one of the glands would clinch it. In the cases we are studying at present tumour of the spleen may be grouped according to the presence or absence of leukaemia.

(a) *Chronic Enlargement of the Spleen with Leukaemia (Spleno-medullary Leukaemia).*—There were 16 cases in this group—12 males and 4 females. The age at onset varied from 22 to 70, four patients being 60 years of age or older, while four were in the third decade of life. The duration of the illness varied from nine months to as many years; the rapidity of course and fatal ending seemed to be less a result of increase in white corpuscles than of diminution of red corpuscles, with consequent anaemia. The onset of the disease is usually gradual, and the patient's attention is first attracted to it by feeling a lump or pain in the side of the abdomen, due to enlargement of the spleen or perisplenitis, or by the symptoms of increasing anaemia, malaise, weakness, pallor, and loss of weight. Haemorrhages occur in the later stages of most cases. The blood picture is that of a secondary anaemia with great increase of the myeloid white cells; early forms not usually seen in the peripheral circulation predominate, pre-myelocytes, myeloblasts, and myelocytes. One of the difficulties in treatment of this condition seems to be that remedies directed to reducing the number of leucocytes (usually by inhibiting production at their source in the bone marrow, by benzol, x rays, or arsenic) at the same time lessen or destroy the red corpuscles which the bone marrow is producing. Antimony, arsenic, benzol, and applications of x rays to bone marrow and spleen all seem of at least temporary benefit, in some cases arresting the progress of the disease and allowing a return to normal health for months or years. Death occurs from progressive anaemia in the chronic cases; in others, there may be terminal irritability

OCT. 2, 1926]

# LEUKAEMIA AND ALLIED CONDITIONS.

of the bone marrow with a crisis of production and dissemination in the blood of immature myeloid leucocytes—myeloblasts or mother cells.

(b) *Chronic Enlargement of the Spleen without Leukaemia.*—This includes a number of diseases of blood-forming organs, which are referred to above—splenic anaemia, Banti's disease, Gaucher's disease, acholuric jaundice of hereditary or sporadic occurrence, pernicious anaemia. Their discussion does not come within the scope of the present paper.

## 3. Mediastinal Tumour.

Excluding instances of aneurysm, hydatid, carcinoma of the bronchus, and secondary growths in the lungs from tumours elsewhere, there were 20 cases of mediastinal tumour, which fall into the following groups.

(a) *Hodgkin's Disease.*—In 9 cases of Hodgkin's disease involvement of the mediastinal glands caused symptoms of pressure in the chest. Even in the mild cases the glands may be enlarged to such an extent that an irritable cough occurs from pressure on trachea and bronchi. Hydrothorax on one or both sides is a frequent accompaniment, and the swelling for paracentesis. X-ray treatment may reduce the histology of the glands, and the symptoms may abate temporarily.

(b) *Lymphosarcoma.*—Six fatal cases showed the histological picture of so-called lymphosarcoma. The course was rapid and fatal. The whole anterior mediastinum becomes more or less filled with a large firm fleshy mass, which surrounds the large vessels, and invades the pericardium and pleura, and may pass beyond the lymph gland capsule, overflowing into the fibrous tissue, and may be found in sections passing between the muscle fibres of the myocardium. The blood often contains an increased number of white corpuscles, usually of the polymorphonuclear type. In some instances, besides the local collection of lymphoid deposit in the mediastinum or the retro-peritoneal space, there is a flooding of the lymphadenoma blood with embryonic white corpuscles. This is the condition described as leucosarcoma—that is, lymphadenoma associated with leukaemia. There is no real line of cleavage between these two conditions. Only one patient in this series of cases showed this condition.

(c) *Fibrosarcoma.*—In four other cases of mediastinal tumour the type cell was fibroblastic, and the cases showed variations from a round-celled, through a spindle-celled, to a fibrosarcoma. The origin of the tumour was in three cases from the periosteum of the sternum, in one it appeared to arise in the fibrous tissue of the mediastinum. Its origin is not from blood-forming tissue, but from the fibrous tissue of supporting structures.

Reviewing this series of cases, we see that in the chronic cases improvement, often for a considerable time, may follow treatment with arsenic, benzol, tartar emetic, and x rays. In the acute cases, and in the long run in the chronic cases, death is due to the disease itself; and as the cause of leukaemia and allied conditions is unknown, specific treatment is not possible.

## GENERAL DISCUSSION.

Professor SKOLTO DOUGLAS (Sheffield) inquired whether Professor GULLAND had found that cases of leukaemia could occur in almost epidemic form. Early experience as a medical student gave the impression that leukaemia was a rare condition in which the myelogenous type prevailed. This impression received some support from Osler, who, writing in 1901, had seen but 24 cases in his hospital practice, of which only 9 were of the lymphatic type. During the last eighteen months in Sheffield 13 cases (12 male and 1 female) of the lymphatic type had been under observation, and 9 cases (5 male and 4 female) of myelogenous type—large numbers for so short a period. In this series the ages of the patients ranged from 2 to 63 years, with half the cases under 20 years, in the lymphatic type and from 18 to 62 years in the myelogenous type. Professor Douglas also asked to what extent the granular reaction could be relied on in differentiating the granular and non-granular cell types, as in his own experience this reaction did not effect all that had been hoped of it.

Dr. R. DONALDSON (London) called attention to the fact that while the textbooks on medicine varied somewhat as regards their treatment of the subject of leukaemia they all made the mistake of giving too rigid a classification. It was only in actual practice that it was realized how utterly inadequate the usual classification was, and how difficult, almost impossible, it was sometimes to name with any degree of precision the type of leukaemia met with in many cases. He disagreed with the view that leukaemia was a sarcomatous tissue, it behaved differently from all other sarcomas. Either there was a primary sarcomatous focus with multiple secondary metastases or there was a universal and simultaneous sarcomatosis of the blood-forming tissue. On the other hand, primary sarcoma of the spleen was rare, while primary tumours of the haemopoietic tissue, unassociated with a leukaemic condition of the blood, were still more rare. An example of this was multiple myelomatosis of bones—a condition which seemed to differ essentially from leukaemia might run added that cases of chronic myelogenous leukaemia might last ten or more years—a thing practically unheard of in true sarcoma. On the other hand, leukaemia might run a fatal course in a very few weeks. Dr. Donaldson considered that there was more to be said for a possible virus or irritant, using the latter term in its broad sense. There might be transmitted by means of cell-free filtrates. On the clinical side, also, there were signs suggestive of an infective condition. For instance, there was the irregular fever, and the occurrence of night-sweats so frequently found in leukaemias—a point not referred to by the previous speakers, except in connexion with Hodgkin's disease. If any further progress was to be made in elucidating the cause or causes of leukaemia investigation must be directed, not so much to a study of the various types of cells met with in the bone marrow and in the blood in cases of leukaemia, but to the discovery of the mechanism which regulated the production of the leucocytes in general. He drew attention again to the well-known variations in the numbers of leucocytes in normal blood—for example, as a result of exercise, food, and metabolism—and to the increase that occurred in a leucocytosis. How exactly was this leucocytosis brought about? Might it not be that in leukaemia the primary change was one affecting the regulating mechanism, and that the varied and varying blood picture was merely the visible expression of this interference? The identification of this regulating mechanism might be the key to the solution of the problem. The mere typing of the blood cells seemed to him at the present juncture quite an unprofitable line of study and one which had hitherto led to nothing but confusion.

Dr. Donaldson agreed with Professor GULLAND that chloroma should be considered as leukaemia, but a special variety of that disease. It differed from the usual types in giving rise to tumours in various connective tissue structures, and it differed also in respect of the excessive amount of oxydase present in the cells. Dr. Donaldson pointed out that this latter could very easily be demonstrated by placing small pieces of tissue taken from the tumour the organs post mortem, not merely from the tumour masses, into a solution containing 100 c.c.m. of 95 per cent. alcohol, 0.5 gram of benzidine, and 0.2 c.c.m. of hydrogen peroxide. Chloromatous tissue immersed in this fluid became instantaneously a deep blue colour—a reaction given by myelogenous leukaemias more slowly and not so intensely, but entirely absent in the case of normal tissue or tissue removed from a case of chronic lymphatic leukaemia. Dr. Donaldson had found this a valuable test, especially in cases diagnosed during life on the blood picture as lymphatic leukaemias, but really myeloblastic; for the tissues in the latter, in spite of the similarity of the blood cells to lymphocytes, gave a positive reaction. He considered that the oxydase reaction would ultimately come to be a very valuable means of distinguishing the lymphatic type of leukaemia from the myeloblastic. At present, perhaps, the reaction was not too reliable as there

were many points to be cleared up in relation to it—as, for instance, the type of reagent to be employed. With regard to Professor Douglas's remarks about the possible epidemicity of leukaemia and his suggestion that leukaemia was on the increase, Dr. Donaldson stated that from an analysis of cases of leukaemia admitted to St. George's Hospital during the last ten years there was no indication of any increase in the incidence of the disease. The classification of these cases was faulty owing to the confusion of myeloblastic with lymphatic types, but under the heading of "acute lymphatic leukaemia" there had been 9 cases—8 males and 1 female—the ages ranging from 5 to 54. Under the heading of "chronic lymphatic leukaemia" there were 7 patients, with ages ranging from 9 to 60, most of whom were females. Under the heading of "chronic myelogenous leukaemias" there were 10 patients, with ages ranging from 28 to 59, of whom 4 were females and 6 were males.

Professor LOVELL GULLAND, in replying to the discussion, said he would like in the first place to traverse very decidedly the statement in Dr. Patterson's paper that x rays or radium caused anaemia as well as a drop in leucocytes in the chronic leukaemias. They might do so if they were improperly used, especially if the dosage was too large, or application was carried on too long; with the proper use of either he had now many times seen the

anaemia improve or disappear without other treatment. Professor Douglas's question as to the value of the oxydase reaction in diagnosis might best be answered by the statement that it was generally useless in those cases in which it was most wanted—in the distinction between the acute myeloblastic and acute lymphocytic types. Some myeloblasts gave the reaction, others did not. He was inclined to think the older myeloblasts showed it, not the younger. He suggested that the acute leukaemias seemed to occur in epidemics. It was certainly true that they often came in runs, but every physician knew that this occurred with a kinds of cases, even with aneurysms and locomotor ataxia. It was certain that many acute leukaemias were not diagnosed. Professor Gulland agreed with Dr. Donaldson in seeing difficulties in accepting absolutely the definition of leukaemia as a sarcomatosis, and had admitted the difficulties in discussing its nature. It was, however, the hypothesis which best explained the facts of the disease. In regard to the causeless remissions in the chronic form it must be remembered that these were often evidence only by the change in the blood; there might be no alteration in the spleen or other organs. They were sometimes merely a cessation of overflow into the blood, without real alteration in the marrow. It was possible to produce blood remission with benzol, for instance, and when the drug was stopped the leucocytes resumed their former figure day or two.

## THE LIVING TISSUE CELL.

BY

T. S. P. STRANGEWAYS, M.A., M.R.C.S., L.R.C.P.,  
Lecturer, Special Pathology, Cambridge University.

DR. STRANGEWAYS said that as a profession they were too apt to regard the human body as a mass of tissue essentially liable to disease and endowed with a consciousness liable to neuroses. It was sometimes wholesome to make an excursion into biological fundamentals, and to reflect for a moment upon what and why the body really is.

The cells of tissues cultivated *in vitro* by the usual method in plasma and embryo extract wandered out from the main fragment and formed a thin film of growing and dividing cells upon the surface of the coverslip. This thin film was very suitable for dark-ground illumination. The cells had amoeboid movement, and showed vividly the mitochondria, nucleus, nucleolus, metabolic granules, and fat. No cell wall, nuclear membrane, or Golgi apparatus could be seen, and in the mitotic cells no evidence of spindle fibres. On the warm stage all the structures in the cell and the cell itself were to be seen in more or less active movement. Anyone watching such a cell would be struck by its individuality and independent behaviour, and would realize, as perhaps never before, that the cell, properly speaking, was an organism complete in itself.

Man, like all other metazoa, consisted of a colony of organisms—the cells. To create a man or any other animal the fertilized ovum produced two lines of descendants—the somatic cells and the germ cells. The sole function of the former was to carry, nourish, protect, and propagate the latter, which constituted the essential part of the organism. In the creation of the somatic colony the fertilized ovum had evinced a far-reaching intelligence inconceivable to our cerebral soma. Researches on tissue culture had shown that all cells were potentially immortal, since tissue under cultivation could be maintained in a state of active growth and multiplication for an indefinite

period. In the body, however, the immortality of the somatic cells was sacrificed for the benefit of the germ cells.

The life of the cell was to a great extent independent of the life of the animal, and the death of the body in no way necessitated the immediate death of its component cells. In an illustration Dr. Strangeways mentioned that recently a colleague happened to need some kidney tissue for cultivation. Previously he had killed a rabbit for experimental purposes and thrown away the body in the dustbin, when owing to the slackness of the dustman, it laid for two days in hot weather. At the end of that period he exhumed it, dissected out one kidney, which he washed in a solution of iodine; he then removed fragments for cultivation, and the cultures grew perfectly.

The method of tissue culture also showed that the somatic cell did not require the control of the organism as a whole in order to build up the various special tissues for which they were set apart in early embryonic life. For example, the isolated eye and limb bud of an early embryonic chick would continue to grow and differentiate in a surprising normal manner when cultivated in a test-tube, although it would be considerably smaller than

allowed to develop under the care of the hen.

Migration and division represented the response of the cell to changes in environment. The cell showed three conditions:

1. Vegetative state ... Environment stable.
2. Amoeboid state ... Environment somewhat changed.
3. Mitotic state ... Environment markedly changed.

In all these three conditions the environment must be favourable, or otherwise the cell would show injury, disease or death.

Vegetative cells might remain quiescent throughout adult life, yet at any moment they might be induced to migrate and multiply. The profession was very familiar with instances of such response.

Cell seen under dark-ground illumination.

OCT. 2, 1926]

# MEMORANDA

The reactions of the cells to their environment might be tabulated thus:

1. Multiplication+differentiation+co-ordination+inhibition = animal.
2. Migration+inhibition=healing by first intention.
3. Migration+multiplication+inhibition=healing by second intention.
4. Multiplication + differentiation + inhibition = innocent tumour.
5. Multiplication+differentiation-co-ordination-inhibition = cancer.

It was extremely desirable to obtain further data concerning the inhibition of growth.  
In the afternoon a practical demonstration was given of the main points in the lecture.

## Memoranda: MEDICAL, SURGICAL, OBSTETRICAL.

THREE "FOREIGN" USES OF OESOPHAGEAL CATHETERS.  
SOMETIMES small points, not mentioned in textbooks, but nevertheless of real value, are worthy of being put on record.

The first use of an oesophageal catheter is to intubate the oesophagus. It is "foreign" to use it otherwise, but here are three uses to which I have put it, and doubtless others have done the same; they may, however, be novel to some.

1. In those distressing cases of an "artificial anus" in the caecal region in which it is highly desirable to short-circuit by an ileo-colostomy, it is occasionally difficult, even when the incision has been made, to be sure of the portion of the ileum which is passing to the caecostomy. If previous to or after the incision an assistant introduces an oesophageal catheter into the artificial anus, it will slip with a little manipulation into the ileal loop, and can be felt and seen through the left-sided incision, thus clearly indicating the portion of intestine which should be anastomosed with the pelvic colon.

2. After the short-circuit has been made it is well to pass an oesophageal catheter through the natural anus, and up through the anastomotic opening into the ileum. This will enable at least flatus to be easily passed during the first twenty-four hours after the operation, and may save the patient a considerable amount of discomfort.

3. When the abdomen has been opened and a volvulus of the pelvic colon has been untwisted, the passage of two oesophageal catheters through the natural anus and up into that portion of the pelvic colon which has been the site of the twist and dilatation will drain the loop, and allow fluids to be injected through one catheter and a recurrence of the volvulus soon after the untwisting is almost certain to be prevented. It is important that the catheters in this instance should be sutured to the anal margin so that they do not slip out before they have completed their work.

W. McADAM ECCLES, M.S., F.R.C.S.,  
Surgeon, St. Bartholomew's Hospital.

## CARDIAC MASSAGE FOR POST-OPERATIVE COLLAPSE.

THE following case appears to be worthy of record in view of the temporary recovery of the action of the heart which followed the use of cardiac massage.

A plating operation was performed on a man, aged 26, who had a compound comminuted fracture of the tibia. There had been considerable haemorrhage, but no cause of anxiety appeared until the end of the operation, when the patient collapsed. Tilting of the table improved his colour, but his breathing stopped almost immediately. Artificial respiration, the use of oxygen, and the injection of pituitrin were without effect. I then opened the epigastrium and massaged the heart with one hand under about two minutes the heart began to beat and the amount of air entering the lungs distinctly increased. The patient's colour became a healthy pink, but the pupils remained widely dilated,

and there was no voluntary respiration. After thirty-five minutes the heart stopped, and further massage failed to restart it. With one hand in the abdomen as a guide, I injected 10 drops of a 1 in 1,000 solution of adrenaline into the heart, using an ordinary hypodermic needle, well pressed home, and inserted close to the sternum in the fourth intercostal space. A few seconds later the heart began to beat again, and continued for half an hour. The patient was given an injection of camphor dissolved in oil, and also ammonia to inhale, but neither seemed to have any effect on the respiratory centre.

The patient died, I presume, of cerebral anaemia, his brain being too toxic or disorganized to respond when circulation of good blood was re-established. The question arises whether he would have lived if I had not lost time in performing artificial respiration, yet if it was customary to practise cardiac massage in every case of collapse on the operating table there would be quite a number of people with a scar in the epigastrium. I should be glad to receive suggestions or criticism.

W. STANSFIELD, M.R.C.S., L.R.C.P. Lond.

## RETROBULBAR NEURITIS (TOXIC).

THE following case of a severe type of retrobulbar neuritis in a moderate smoker presents points of interest.

X.Y., aged 51, in the "trade," complained that his eyesight had been failing for two years. He had been a soldier in India for several years, and was invalided out of the army on account of injury to the spine. He was referred to me in March, 1926, by Messrs. Charnley and Sons, opticians, Bedford. His vision then was: right eye, 6/24 with difficulty; and left eye, less than 6/EJ. In each eye there was a large central scotoma for red, blue, and green, with contracted fields for white.

In the centre of each disc, more marked in the left eye, was a small pale area, in which the lamina cribrosa was evident. The fundus was otherwise normal, as were the remaining structures of the eyes. There was no evidence of peri-orbital sinus infection. The teeth were good. It was suggested that the Wassermann reaction should be tested, but this was declined. The patient was a beer drinker, and a moderate smoker. He never smoked shag or the heavier tobaccos, but only a medium Virginia tobacco.

The diagnosis of retrobulbar neuritis of toxic origin was made. As he thought he would become blind in any case he was with difficulty persuaded to be a total abstainer and non-smoker for twelve months. He was referred to his own doctor for the usual treatment of tobacco amblyopia, with strychnine, suitable diet, and purgation, etc.

Four months later, Dr. F. Bolster, C.M.G., kindly sent the patient to me for further examination. I found that vision was now normal in the right eye—6/6 without correction, and colour vision was normal. In the left eye vision was 6/24 without correction; vision for red and blue had returned and there was a small central scotoma for green remaining. There was an old-standing external strabismus in the left eye.

In March he wore plus 7.0 D. sphs. and could only read large print even with these magnifying glasses. In July he could read J.1 with plus 2.0 D. sphs., his normal correction. At neither examination were there any associated signs of chronic disease of the central nervous system.

A diagnosis of progressive optic atrophy should be made with diffidence, even in a moderate smoker of medium Virginia tobacco, until toxic retrobulbar neuritis can be definitely put out of consideration. In this case the diagnosis was rendered more difficult by the fact that the visual acuity differed considerably in the two eyes. It would seem as though the deterioration of vision in the two eyes had proceeded at a uniform rate, as is usual in tobacco amblyopia, the resultant difference in visual acuity being due to the partial amblyopia in the left eye, which was present when the toxin commenced to affect vision.

C. G. KAY SHARR, M.D. Leeds.

## HERPES AND VARICELLA.

IN connexion with Dr. W. J. Meldrum's memorandum on herpes and varicella (August 14th, p. 362) the following case would appear to be of some interest.

On June 15th, a boy, aged 9 years, developed unilateral intercostal herpes, which gradually subsided. On July 2nd the remaining five children in the family, including a girl aged 12, showed definite chicken-pox, whilst the lad who suffered with herpes was unaffected.

It will be noticed that the time between the herpes and chicken-pox is seventeen days. This seems too remarkable to be a mere coincidence.

London, N.13.

## Reviews.

### A BIPOLAR THEORY OF LIFE.

STARTING more than thirty years ago on a research into the cause of death, the distinguished American surgeon GEORGE W. CRILE became convinced that it was essential first to understand the nature of life, and since then this great problem has continuously engaged his attention and that of his co-workers. The circulation and respiration, blood chemistry, cytology, and biophysics, were examined successively, and he has now brought out a volume on *A Bipolar Theory of Living Processes*.<sup>1</sup> The length and painstaking nature of the research on which it is founded entitle this monograph to serious consideration, especially as it is frankly admitted that the conclusions have not been finally proved. Evidence is brought together in favour of the view that man and animals are bipolar mechanisms and that the organism is not only driven by electricity, but that it was originally called into existence and constructed by electric forces.

Investigation of the cardio-vascular and respiratory phenomena satisfied the author that surgical shock was not due to primary change in these systems. Incidentally his researches led to certain practical conclusions as to the prevention of surgical shock by nerve blocking and as to the value of blood transfusion and its application. Another conclusion reached was that stimulants, so called, as a class increase fatigue and exhaustion, whereas morphine minimizes these effects. Work on the chemistry of the blood showed that the acid-alkali balance of the organism has a vital significance, and from cytological observations it was concluded that the nucleus of the cell is relatively acid and the cytoplasm relatively alkaline, the nucleus and the cell being surrounded by an extremely thin dielectric membrane. The two organs which most promptly succumb to lethal influences seemed to the investigators to be the brain and the liver. With the help of biophysical examination it was concluded that the cells of the body are electric cells in which the comparatively acid nucleus is the positive pole and the cytoplasm the negative pole, and that the maintenance of this acid-alkali balance between the nucleus and the cytoplasm—electric potential—is essential to life; this balance is both due to, and controls, oxidation. The conclusion that the individual cells, like the living organisms, in which the brain is the positive and the liver the negative pole, are bipolar electric mechanisms, would answer the question asked as long ago as 1835 by Becquerel and Breschet, "Are the vital forces of an electric or chemical nature?" As the liver, being the negative pole, accumulates waste products and so keeps clear the great circuit between it and the brain, any failure in this hepatic function will impair the circuit, and as a consequence the tissues of the body will no longer receive the electric discharges on which their structure, activity, and life depend, and death follows. The specific characteristic differentiating the living organism from the non-living materials composing it is regarded as the frequency and force of the electric discharges. Life is a dynamic not a static phenomenon.

This bipolar interpretation is applied to memory, intoxications, fever, and cancer. The cancer cell has a higher electric potential than normal cells, and therefore, it is concluded, multiplies at their expense. The higher incidence of malignant disease in advanced life is explained by the generally falling metabolism diminishing the low defence of the tissues of low capacity and causing an inequality in an already wavering balance between the electric capacity of neighbouring cells. The bipolar theory is also held to explain the usual incidence of sarcoma in early life. The appendixes, which occupy more than a third of the volume, contain the experimental data already published by the author and his collaborators in support of this thesis, quotations from literature bearing on the problem, and a consideration of the energy transforma-

tions in the body from an electrical standpoint by J. O. Perrine, Ph.D.

The book is a monument of patient research on a subject as difficult as it is important.

### NUTRITIONAL DISORDERS OF CHILDHOOD.

THE third volume of the series of clinical studies in children<sup>2</sup> published by Professor P. NObécourt treats of disorders of nutrition and growth, and contains some twenty clinical demonstrations; it deals with cases of cretinism and thyroid deficiency, gigantism, and other pituitary disorders, different types of obesity, diabetes, acetonæmia, chronic articular rheumatism and fragilitas ossium. Each chapter is the record of a lecture or demonstration; it begins with the presentation of a case or group of cases with their essential details and illustrated with photographs and clinical charts, and ends with a general discussion of the disease, giving references to the literature. The conditions he deals with are for the most part rare, but, in addition to the striking structural changes they exhibit, they raise points of great interest in physiology and medicine; and the method of presentation, beginning with a diseased individual, and proceeding to a discussion of the diseased process, is well suited to maintain the interest of the reader, laying before him the grounds of diagnosis, and from diagnosis passing naturally to treatment, prognosis, and pathology. French medical literature has given us many brilliant examples of this kind of medical writing, and Professor NObécourt takes a worthy place in that succession. Both by his great clinical experience and his extensive acquaintance with the literature, he is well equipped for the writing of such a book of clinical studies. This volume, dealing with disorders of growth, is up to the high standard of clarity, conciseness, and interest which was reached in his two previous volumes on diseases of the respiration and of the circulation. As a record with commentary of the rare conditions with which it deals it is of great interest and value.

*Nervous and Mental Disorders from Birth through Adolescence*,<sup>3</sup> by Dr. Sachs, is the mature presentation of his long clinical experience in this subject. It is much more than the revision of the last edition of his *Nervous Diseases of Children*, published in 1905, though it naturally incorporates much of its material. Since that date there has been much progress in neurology and a great accumulation of literature, and in the greater leisure secured by release from hospital practice Dr. SACHS, with the assistance of Dr. HAUSMAN, has written what is actually a new book on the subject. The arrangement of the subject is somewhat different. The first portion deals with anatomy, physiology, and the methods of clinical examination. The next and largest section is devoted to organic diseases of the nervous system as a whole, in which there is no definite separation of brain, spinal cord, and peripheral nerves; this is justified by the fact that such diseases as infantile paralysis and epidemic encephalitis may affect any part of the nervous system, central or peripheral. In this section will be found also a chapter devoted to chorea and choreiform diseases, an inclusion which represents a change of neurological opinion. The remaining sections deal with functional and toxic diseases, such as convulsions, epilepsy, headache, etc., with endocrine disorders and trophoneuroses, and with mental conditions, including the neuroses and psychoses, insanity, and the various forms of congenital mental defect.

Infancy and childhood is the period when infections of the nervous system prevail, and when congenital defects, in their multifarious variety are met with, and a treatise on nervous disease at this time of life must deal with a large number of conditions, some of which are common and therefore important, such as infantile paralysis and tuberculous meningitis, while others, such as the hereditary and familial affections, though rare, are not only of great

## REVIEWS

OCT. 2, 1925]

clinical interest, but also throw light upon the physiology of the nervous system. In this book, assisted by a number of good clinical and pathological illustrations, Dr. Sachs has successfully presented a large and complicated subject in a very interesting way. On the subject of nervous disorders in childhood and adolescence, he speaks with the authority of long clinical experience, and with a wide knowledge of the literature; indeed, an appendix to each chapter gives a full bibliography of the subjects dealt with. In an interesting and valuable chapter he traces the development of the normal mind in infancy, childhood, and youth, and takes the opportunity of expressing forcibly his opposition to the Freudian doctrines of child psychology, and especially to their application in psycho-analysis. The book is an authoritative, a fairly full, and an interesting exposition of a large and important subject.

Sex diseases in children,\* by Dr. FISCHER-DELOY of Frankfurt, and Drs. KRAMER and LANGER of Berlin, is a small volume of a hundred pages dealing with congenital syphilis and gonorrhoea in children. It gives a brief account of their clinical manifestations, and deals also and more fully with their train of consequences for the individual and their wider family and social effects. It is written partly for medical men, but more especially for the instruction of parents, social workers, and teachers, in the hope that with wider knowledge its curative and preventive treatment may become more effective.

## REASONED HISTOLOGICAL TECHNIQUE.

Of the two types of book dealing with histological technique, one consists mainly of rule-of-thumb prescriptions which will enable the student to prepare a presentable slide and pass his practical examination without discredit; the other explains the scientific principles of the subject and builds thereon a superstructure of directions which will enable him to become efficient in what is essentially an art, and equip him for its subsequent application in scientific research. Of the latter type CARLETON's *Histological Technique*† is a good example. The general plan of the book does not differ from that usually adopted in such works. There is a chapter on type-methods of normal histology, including fixation, embedding, section-cutting, and staining. This is followed by a chapter on accessory methods—dark-ground illumination, histo-chemical tests, injection methods, and intravital staining. Then the various tissues and organs of the body are taken in order and the most suitable methods of preparation in each case described; and finally a chapter is devoted to the technique of morbid histology, including methods for the identification of micro-organisms and other parasites.

The book, however, embraces a wider view of the subject than is usually adopted in treatises on histological technique. Thus the author has thought well to make a departure from current practice by inserting chapters on the cell in relation to histological technique, emphasizing the conception of cells and tissues as complex colloidal entities which are only too readily altered by the treatment to which they are subjected. Further, an interesting chapter, contributed by Mr. F. HAYNES, has been added, giving an elementary account of the theory of staining—a complex subject, but which lies at the very foundation of an adequate knowledge of the technique. While taking a broad view of the subject, the author has not overlooked the importance of attention to minute details. A knowledge of the histological technique depends largely on a knowledge of various small "tips," and many of these useful details have been added as notes appended to the descriptions of the various methods. Again, the success attendant on technical manipulations is to a considerable extent proportionate to the worker's knowledge of small hidden

difficulties, and it has been the author's aim to point out these and indicate the means of avoiding them. The book will prove a useful and reliable guide to the serious student, encouraging him to work by the understanding rather than by rule of thumb.

## GUY'S HOSPITAL REPORTS.

Of the ten articles in the third quarterly instalment of the *Guy's Hospital Reports*‡ the first four relate to Thomas Addison; Sir William Hale-White's account of this distinguished investigator, who in 1828 started systematic note-taking by the clinical clerks, is noticed elsewhere (p. 607). Dr. Arthur Hurst reports the results of his investigation of eighty-seven cases undertaken to determine the relative frequency of primary constitutional achylia and of achylia secondary to gastritis in Addisonian anaemia, and of achylia combined degeneration of the spinal cord, and the glossitis syndrome of William Hunter. Dr. Maurice Shaw records a case of apparent recovery from Addisonian anaemia and of return in the hydrochloric acid in the gastric juice, the only question being whether or not the three years should be regarded as an exceptionally long remission or as evidence of cure. The remaining member of these first four articles deals with a case of Addison's disease associated with hypothyroidism and vitiligo; unfortunately, though the case terminated fatally, a necropsy was not obtained. Dr. Norman Burgess and Mr. E. C. Warner suggest that the hypothyroidism was secondary—and possibly compensatory—to the adrenal disease. Dr. J. J. Conybeare supplements his experiences of American medicine previously summarized in these *Reports* by a description of the practice of radiology in the hospitals of the United States, and brings out the points of difference from practice in this country. Professor Pembrey and Mr. E. T. Conybeare bring forward experiments on animals, under controlled conditions as regard diet, dealing with the respiratory quotient—namely, the relationship of the volume of oxygen absorbed to the volume of carbon dioxide discharged. Dr. Hugh Barber of Derby describes renal dwarfism from his experience of seventeen cases, and, after discussing the nature of so-called late rickets, concludes that most, if not all, of the cases so described have been renal dwarfs. Drs. H. W. Barber and F. D. Howitt's observations on light sensitization of the skin are extremely interesting, and are prefaced by a good description of the literature; they divide all cases into (i) those in adults due to a bacterial toxin or possibly a bacterial product absorbed from the intestine, and (ii) the juvenile cases in which the sensitizing agent is often, if not invariably, a porphyrin. Drs. Arthur F. Hurst and Adrian Stokes describe with illustrations a case of hypertrophic gastritis (gastritis polyposa) in which gastrectomy was followed by recovery. Writing from the New Lodge Clinic on dental root infections, Dr. F. A. Knott and Mr. A. Ll. Spencer-Payne find that streptococci are constantly present in early infections of the roots, but that no specific strain of streptococci is associated with arthritis or peptic ulcer, and that the production of systemic and metastatic infections depends more on the presence of diminished local resistance than on specificity or selectivity of the streptococcal strain found in them.

## EVOLUTION, GENETICS, AND EUGENICS.

The second edition, after six impressions of the first, of the successful summary entitled *Evolution, Genetics, and Eugenics*,§ by HORATIO HACKETT NEWMAN, professor of zoology in the University of Chicago, will be welcomed both by general readers and by students as an unbiased textbook, which contains between two covers material otherwise obtainable only by consulting two or three separate works. It consists of five parts, the first three dealing with the history, evidence, and causal factors of

§ *Evolution, Genetics, and Eugenics*. By Horatio Hackett Newman. Chicago, Illinois: University of Chicago Press; London: Cambridge University Press. 1925. (Med. 8vo, pp. 22 + 629; 23 figures. 17s. 6d.)

evolution, the fourth with genetics or the modern study of evolution by means of experimental breeding, cytology, and the statistical method, which is concerned with heredity and variation more or less to the exclusion of environment and training.

In the fifth and last part, on eugenics, the old but still interesting question of the relative importance of heredity on the one hand, and of environment and training on the other hand, is discussed. The author mentions certain fallacies which, he holds, are inherent in Galton's attempt to elucidate this problem by the collected data of identical and fraternal twins, and describes his own observations on more than two hundred quadruplets of the nine-banded armadillo of Texas, which lead him to the conclusion that the average potency of heredity is about 93 per cent., as compared with 7 per cent. for both environment and a third factor which, he suggests, might be called the distributional or developmental inaccuracy. The order of the presentation of the evidences of evolution has been altered in this edition as the result of further teaching experience that, for an appreciation of the palaeontological and geographical data, the student must first have a knowledge of the principles of morphology and comparative anatomy. In the section on genetics the Mendelian theory and the laws of sexual reproduction are clearly set out with many diagrams, as are the arguments for and against the inheritance of acquired characters, which bear on the controversy between the mutationists and the Lamarckians. Accounts of the recent anti-evolution campaign and the Scopes trial in America are among the additions to this edition.

This handbook is based on more than twenty years' experience in teaching students, and contains numerous extracts, sometimes of considerable length, from authorities on the subject. The evidence thus collected is impartially presented to the reader, who is then left to form his own decision on disputed points.

### THORPE'S DICTIONARY OF CHEMISTRY.

VOLUME VI of THORPE'S *Dictionary of Applied Chemistry*\* covers the range of initial letters S and T (to tetra). In our comments on the preceding volumes of this edition we have remarked on the catholicity of the subjects treated. That now before us presents the same extensive variety, which we may illustrate by reference to the following instances: an article on the Japanese beverage sake describing its composition and mode of preparation, and adding incidentally the information that it is usually taken hot immediately before meals; a monograph on sewage, showing the applicability of various methods of treatment for purification, and a treatise on the subject of solution discussing its theoretical aspects. Perhaps the most striking example of the thoroughness of the work appears under the heading of sugar, where space is found for the botanical description of the sugar-cane and sugar-beet, of methods of production and refining, with illustrations of manufacturers' plant and of statistics of production and methods of analytical examination, including the description of several polarimeters; lastly, a full account is given of the several methods by which the percentage of sugar may be determined in blood. There follows a discussion on insulin as a means of controlling blood sugar in diabetes mellitus, written by Professor Barger.

Notwithstanding the great variety of matters that come under the heading of applied chemistry, it is remarkable to note the large number directly related to medical science. All these appear to contain the newest information contributed from authoritative sources. There is an article on synthetic drugs, also written by Professor Barger, in which production by synthesis is discussed in its relation to therapeutic and pharmacological needs, and a catalogue of synthetic drugs, reciting their uses, advantages, and imperfections, is provided. This volume is altogether a notable addition to a notable series.

\* *A Dictionary of Applied Chemistry*, Vol. VI. By Sir Edward Thorpe, B. Sc., LL.D., F.R.S., assisted by eminent contributors. Revised and enlarged edition. London and New York: Longmans, Green and Co. 1926. (Med. 8vo, pp. viii + 751; illustrated. £3 net.)

### BIRTH CONTROL.

It is a relief to read a book on birth control which is written in dignified and measured language and free from extravagance. The little book on *Birth Control and the State*,\* by Dr. C. P. BLACKER, is a plain statement of the arguments put forward by the protagonists and the antagonists, and he puts the assertions of the antagonists first; to them "it is a pernicious and unnatural practice leading to the degeneracy and, ultimately, to the extinction of the race." He gives the reasons underlying this sweeping statement and then the arguments on the other side. One difficulty he points out exists, "that from the technical point of view a really satisfactory contraceptive does not yet exist." Thereafter the author leads the reader up to the purpose of the book, which is to convince him that the great danger of civilization lies in unequal overpopulation. Dr. Blacker points to the past and present dangers due to the excessive fertility of the Japanese, the effects of ancestor worship, and to what we know happened in Germany. He maintains that only by an international adjustment of population that can be attained by biological effects can there be a cessation of these mad interludes. He believes that the Ministry of Health should take a hand in instructing the population. Cold official action in this regard would reduce the tension of the quarrel between the opponents and advocates. The practice is well known amongst the better educated of the people, but by all accounts scarcely known among the masses. Yet he adduces evidence, some of it novel, that the excessive fertility found amongst the less affluent sections of the people is not desired by them. But his great argument in favour of limitation is that thereby international relations may be improved: "In this way the medical profession, in whose hands the health of each community lies, would take the first step in the direction of an international control of population, and would thereby lay the basis for a genuine and permanent world-peace."

This is a book that could be read by the most delicately minded maiden lady; it would not bring a blush to her cheek, but it would certainly "put her wise" to the purpose of birth control.

### NOTES ON BOOKS.

A SIXTH edition, revised by Dr. ARNOLD CHAPLIN, has been issued of JOHNSON SMITH'S useful book *A Medical and Surgical Help for Shipmasters and Officers in the Merchant Navy*.<sup>10</sup> Its aim is to afford help in the treatment of injury and disease occurring at sea or under conditions in which there might be no possibility of professional assistance. The subject is treated in an interesting way, and in language easily understood by the layman. Preliminary chapters deal with the preservation of health and the treatment of illness on board ship. The medicine chest is then described, and there is a reasonably brief chapter on the construction of the body. The rest of the book deals with diseases and injuries of various parts of the body, and with poisons. A useful chapter on cooking on board ship, with recipes for invalids, concludes the volume. The book must be of the utmost value to the masters and officers of the mercantile marine when faced with the necessity of rendering first aid in cases of sickness or injury.

The textbook which Drs. FEINBLATT and EGGERTH have written, entitled *Clinical Laboratory Medicine*,<sup>11</sup> contains an account of all the ordinary laboratory tests which might be done by a physician with a little special training in laboratory methods. Other subjects are dealt with also which are perhaps better left to the pathologist—such, for instance, as the Wassermann test—but even these more technical subjects are handled from the clinical point of view. The descriptions are brief and supplemented by references (which, by the way, are most inconveniently placed so as to interrupt the text). But apart from this the book is well put together and adequately

THE BRITISH  
MEDICAL JOURNAL 601

illustrated. Looking through the tests described, an English reader will be struck by the fact that the popularity of certain methods of analysis has a curious geographical distribution. In urine analysis, for instance, the American methods often differ from our own, and these again from French or German. In each country, no doubt, certain methods have been popularized by pathologists in authoritative positions. This book may be said to give an exposition of the American point of view.

In preparing the fifth edition of his textbook on *Diseases of Infants and Children*,<sup>12</sup> Dr. CHAPIN has found a new associate in Dr. ROYSTER, who replaces the late Dr. Pisek. The popularity indicated by the call in America for a new edition is probably due to the condensed, and yet complete, presentation of the subject. The plan and order of the chapters is that usually followed, general considerations, infant anatomy and physiology, and infant feeding being dealt with, and thereafter diseases under the various systems described. There are many illustrations, but their average standard is rather low. Brevity is the soul of wit, and it is far better to err in brevity than in tediousness, so long as a proper standard of clearness and accuracy is maintained. The chapters on digestive disturbances, healthy infant are well done, but that on digestive disturbances in the infant is too short to be adequate. Important and common diseases, such as tuberculosis, rickets, end even pneumonia, deserve a fuller exposition than they receive; epidemic encephalitis is dealt with in a single page. The authors are not lacking either in knowledge or experience, but they do not select their material so as to achieve accuracy and clearness. The price of the book is high.

Miss DOROTHY MORTON has compiled a useful little book of recipes entitled *Invalid Diet*.<sup>13</sup> In it are found selections of dishes suitable for patients who are anaemic, constipated, dyspeptic, diabetic, or rheumatic. With the help of this book the practitioner need never be at a loss when asked to vary the diet of his patient; and the invalid's friends can be advised to keep within the ambit of the recipes recommended. Miss Morton gives some useful hints on cooking and the care of utensils. We disagree, however, with her statement that "60 fluid drops equal 4 oz.," which is sufficiently contradicted by the next statement that "1 tablespoonful of oil or liquid equals 4 oz." We are doubtful about the necessity of recommending by name a particular variety of bread and a particular brand of raisin. And the statement that the constipated must drink copiously of pure water needs the qualification that the water should not be too hard.

Dr. WITTELS, we gather, is a German-Austrian. Perhaps this accounts for the jaundiced view he takes of society in his book *An End to Poverty*,<sup>14</sup> and for his resuscitation of the scheme for universal civil service devised by the late Josef Popper Lynkeus. The lot of the professional man in Austria after the war was hard; instinctively he would turn to any theory which might promise an alleviation of his troubles. So it is that with violent diatribes against the pseudo-profound, the obscurantists, priests, and philosophers, noblemen, and the curious category of kings, generals, bishops, and bank directors, Dr. Wittels advocates the adoption of a system of universal peace conscription. Under it every individual would be enrolled in a "subsistence or minimum army," men serving from the ages of 18 to 30, women from 18 to 25. This subsistence army would be engaged in providing all the inhabitants of the country with food, clothing, and shelter for the whole of life, and with medical attendance and nursing when needed. For the purpose of providing medical attendance the doctors would be enrolled in a State service during the period of their conscription. A sample of the kind of ideas Dr. Wittels favours is his proposal that there should be one of these conscripted doctors for every three hundred persons. On the completion of service the men and women of the minimum army would be absolutely free, and could become capitalists or anything else they might choose. "They could spend their time in any way they pleased." As everyone will agree that the abolition of poverty is a desirable ideal, consideration may justly be given to any proposal to this end, however Utopian. But in the presentation of the case hysterical outbursts should be avoided. ENER and CRAN PATZ are diligent and, on the whole, very competent translators, but, as we have remarked before, it is a pity that they do not make a better selection of books to translate.

## Nova et Vetera.

### THE BAD END OF A POLITICAL ANATOMIST.

Or the valuable series of studies in the history of medicine which are being issued under the editorship of Professors Sudhoff and Sigerist, Part II, on Joh. Jessenius,<sup>1</sup> is the work of Professor Pick of Prague. Pick had been engaged for many years in collecting material for a history of the medical faculty of the University of Prague, and the present work was undertaken as a necessary preliminary, Jessenius having been one of the early chancellors. It is a sad reflection that Pick did not live to see his work given to the world.

Jessenius, who traced his descent from the old nobility of Hungary, was born in Leipzig in 1566, six years before the massacre of St. Bartholomew, an event which affords an indication of the spirit of the times. Religious cleavage and political upheaval were the prominent features of the period, and Jessenius, a man wholly devoted to medical science and literature, a Protestant but free from every trace of religious rancour, and totally lacking in the qualities of the political agitator, found himself, by the accidental circumstances of his position, drawn into the very vortex of the storm, with tragical consequences to himself. These troubles, however, did not come upon him until past middle life, and, for the rest, he was free to carry out the work that lay nearest to his heart. He obtained his early medical training in Wittenberg and his native town of Leipzig, where he wrote his first dissertation, "On the Immortality of the Soul."

Before taking his doctorate, however, he travelled into Italy to complete his education under the great teachers of the University of Padua. There he came under influences which fixed his ambitions; he conceived a desire to become instrumental in disseminating the learning of the Italians in his own country and, more particularly, to introduce into Germany the systematic teaching of anatomy by means of public dissections of the human body. The obstacle of religious tests prevented his receiving the doctorate, and although he had testimonials from many of the Paduan professors, showing him to be more than qualified for the diploma, these were of little service to him in the German universities. It was open to him to obtain the diploma of "doctor bullatus" from certain professors who were authorized to confer medical degrees, legitimatize bastards, and the like, but the universities did not favour this cheap mode of graduation (the post-laureateship had on one occasion been conferred at the price of eight thalers). Jessenius, with much practical shrewdness in so young a man, adopted a course which was sometimes successful in those days, when dedications were somewhat susceptible to flattery. He obtained the good graces of the Emperor by dedicating to him a treatise on "Human and Divine Philosophy," and he was also fortunate enough to gain the ear of the Grand Almoner. In the sequel the Emperor, as a special favour, conferred on him the full doctorate, with the right to occupy professorial chairs in any part of the Holy Roman Empire, authorizing any obstruction met with in the exercise of the same to be countered by a fine of seventy gold marks. In like manner the dedication of two books on Aristotle to the celebrated and influential theologian Polycarp Leyser is considered to have gained him the chairs of anatomy and surgery in the University of Wittenberg, at the early age of 29. Two years later he was appointed Rector of the University. His position being assured, he rapidly proved

<sup>1</sup> Joh. Jessenius de Magna Jessen: Arzt und Rektor in Wittenberg und Prag Hingerichtet am 21 Juni, 1621. Ein Lebensbild aus der Zeit des Dreissigjährigen Krieges von Prof. Dr. Friedel Pick. Studien zur Geschichte der Medizin. Heft 15. Leipzig: J. A. Barth. 1925. (8x11, pp. v + 315; illustrated. 1.20.)

himself to be a man of learning and an author of distinction, not only in medicine and surgery, but in theology, history, and philosophy also; in his particular art he was soon recognized as one of the leading surgeons of the day. He acquired an extensive practice among the nobility and in the higher circles of society, and was appointed physician to the Court. In educational matters he lost no opportunity of holding his favourite public Anatomies or Dissections, and was indefatigable in encouraging disputations, as they were called, or public discussions on medical subjects, accounts of which in a great many instances were subsequently published, and remain as valuable records of the medical knowledge of the period. He attached great importance to *post-mortem* examinations, and an excellent scheme which he devised, of distributing notes of these with their clinical histories to a large circle of his fellow-practitioners, with the object of supplementing their limited experience, entitles him to be considered a pioneer in medical journalism. Although not himself an original thinker, he undoubtedly did much, by his numerous writings and his personal influence, to bring his countrymen abreast of the times in medical knowledge. His principal work was a treatise on surgery, written in Latin, and the fact that it was considered worthy of translation into German more than fifty years after his death is sufficient evidence of the high estimation in which it was held. He had a sound judgement in surgical matters, and is regarded as the founder of rational surgery in the German universities. He freed himself from many of the prejudices that were rife at the time, more particularly from the prevalent excessive use of drugs and the evils arising from the tendency to caste within the profession.

During his residence in Wittenberg the interest of Jessenius turned towards the University of Prague, the oldest foundation of the kind established on German soil (founded in 1348). The fame of the old university had greatly declined; its medical college was wellnigh extinct, and what remained was degraded to the lowest degree. Jessenius was moved to attempt its regeneration, obtaining, as a preliminary step, permission to hold a public Anatomy there, the first, as he was proud to think, that was ever held in the university. It was a notable function. The Dissection commenced on June 8th, 1600, before an audience of nearly a thousand persons, including a number of the most distinguished and learned men of the city, students, and gentry; and, being continued from day to day, terminated, with God's help and amid general applause, on the 12th, a gentle rain at nights ensuring the necessary coolness of the atmosphere, and clear skies by day permitting the dissections to be held in the open. The observations noted in this celebrated Dissection formed the basis of a "Treatise on Anatomy" which Jessenius wrote in praise of that science and which is considered to be one of his greatest works. He gave several similar Anatomies in Prague, but he was never a professor in the university; on the other hand, his influence gave a great impetus to medical studies. His Anatomies, more especially, were highly valued and often extolled in Latin verse by the poets of the time, and it is related that he received a poetical invitation to a dinner at the university on February 22nd, 1605, given in his honour and in recognition of his anatomical services in Prague.

In 1617 he was appointed to the Rectorship, but in the following year those political events occurred which brought his academical labours to an end and were to prove his ruin. The troubles had their origin in certain religious concessions which the Emperor had granted to the Protestants of Bohemia. The latter appear to have overstepped in some minor degree the limits of freedom conferred on them, with the result that two of their churches were ordered to be demolished. This ill advised measure aroused the indignation of the Praguers and, what was more serious, gave an opening for the activities of the extremists in the city. The Estates were convened; two of the Emperor's representatives, who were held responsible for the outrage, were denounced and sentenced to be "defenestrated"; a delegation was sent to the palace, and the obnoxious Statthalters and their secretary were un-

ceremoniously flung from the palace window into the courtyard, sixty feet below. This occurrence naturally gave offence and is generally regarded as the proximate cause of the Thirty Years War. The irritation and suspicion of the Bohemians were further increased by the recent succession of Ferdinand II, a determined champion of Catholicism, to the imperial throne and the thrones of Hungary and Bohemia. An embassy was immediately dispatched to the Hungarians, with the object of delaying the coronation, the intention being to gain their concurrence in forcing the king to dismiss his evil counsellors; such at least was the ostensible reason, though there seems little doubt that the real object was to draw the neighbouring countries into rebellion.

It was at this juncture that Jessenius entered the tortuous path of politics, by consenting to act as ambassador in the mission. He was coldly received in Hungary, and ultimately arrested and carried to Vienna, where he remained a prisoner for six months. But although in this affair he was treated as suspect, there is good evidence that he had no thoughts of rebellion at that time. In a prayer which he distributed to the schools in Bohemia shortly before the mission, he referred to the Emperor as "our gracious Lord and King"; when accused in Hungary of desiring to set that country in a blaze, he retorted that it was a sesquipedalian lie (a lie foot and a half long); when interrogated by the Imperial Chancellor during his imprisonment in Vienna, he expressed the hope that of the three available measures applicable to the situation in Bohemia—namely, dictating, physic, and flogging—the Emperor would choose the mildest measures and not the latter. The Chancellor reminded him of the daily increasing excesses of the Bohemians; Jessenius, in fact, does not seem, at this time, to have possessed that political acumen which is required in order to detect the real beneath the ostensible. The rest of the story is soon told. The next prayer that he distributed to the schools contained no reference to the Emperor; second mission, headed by himself, had frankly for its object the drawing of the neighbouring countries into rebellion; the battle of the White Hill was fought and lost, and Jessenius and many of the citizens of Prague found themselves prisoners under sentence of death. The sentences varied in severity; that on Jessenius was, apparently, the most severe—to have his tongue cut out and to be quartered alive. This was so far mitigated that decapitation preceded quartering. Jessenius preserved his courage and his good humour throughout this ordeal. He regretted that his tongue, which had so often uttered words deemed worthy of approbation before emperors, kings, and princes, should be cut out; for the rest he cared little, and "by this time to-morrow, gentlemen," he said, addressing his friends, "I shall, unlike yourselves, have no need to trouble about the price of corn, or whether there is to be peace or war."

Very little is known of the private life of Jessenius. A description of his wife has been preserved, and is of interest as exhibiting, in contrast with our present conceptions, the feminine ideal of the time. We are told that "she was deeply read in the Word of God, and, having no children, spent the greater part of the day in hymn and prayer and in the study of the Scriptures. She honoured and was obedient to her husband at all times, was ever faithful to him, and, most important of all, forbearing and indulgent in the management of him, never taking anything amiss or opposing him, but regarding his will as law. She was circumspect and clean in her household economy, and sought refinement rather than luxury. She never shouted at the servants, but controlled them with a kindly eye. Discreet as Abigail, she seldom walked abroad, and then always with a serious and modest demeanour."

Beyond a few trifling cuts and bruises, the defenestrated Statthalters experienced no ill effects from their fall. This seemingly miraculous escape from the jaws of death was, of the evidence of eye-witnesses of the occurrence, ascribed to the direct intervention of saints and angels, aided, as some supposed, by the fact of their having fallen on a large dung-heap which lay at the foot of the castle.

# MALARIAL TREATMENT OF GENERAL PARALYSIS.

OCT. 2, 1926]

## THE VALUE OF MALARIAL THERAPY IN DEMENTIA PARALYTICA.

PRELIMINARY REPORT FROM THE LONDON COUNTY MENTAL HOSPITALS SERVICE.

The following preliminary report deals with the results of three years' malarial treatment of general paralysis in the various mental hospitals of the London County Council. In order to furnish comparable evidence as to the frequency of remissions in untreated cases figures have been obtained from four of the L.C.C. mental hospitals dealing with cases admitted during the three years from August 1st, 1920, to July 31st, 1923, who were diagnosed clinically as being general paralytics and who showed positive Wassermann reactions in the cerebro-spinal fluids. The fact that the period under review immediately precedes that in which malarial treatment was undertaken is in some degree a guarantee that changes of administrative policy as to the discharge of patients or any marked attenuation of the severity of the disease are not a factor for the results obtained during the period of malarial treatment.

TABLE I.

| Period of Observation.               | Number Admitted. | Number Discharged as Improved. | Number Died. |
|--------------------------------------|------------------|--------------------------------|--------------|
| August 1st 1920, to July 31st, 1923. | 227              | 6 (2.6%)*                      | 141 (62.1%)  |

\* Of these one was readmitted as relapsed.

Since February 3rd, 1923, when the first paralytic to be treated with malaria in the London County Mental Hospitals Service was inoculated at Cane Hill Mental Hospital, malarial therapy has been carried out continuously in the London County service.

This report, however, deals with the first cases treated, the more recent inoculations being omitted. In Table II are shown the results of malarial therapy in all cases whose course of eight or more febrile paroxysms had been completed by August 31st, 1925. The shortest period during which any patient in this table has been watched since the termination of the malaria is six months, but the majority of the cases have been watched for a much longer period. The term "discharged" includes all patients who have been sufficiently well to be sent to their homes; transfers to other institutions are not included.

TABLE II.—Results obtained with Malarial Treatment.

| Mental Hospital. | Number Treated. | Number Discharged | Number Died. | Reported by          |
|------------------|-----------------|-------------------|--------------|----------------------|
| Bexley ...       | 35              | 14 (40%)          | 6 (17.1%)    | Dr. D. R. Alexander. |
| Cane Hill ...    | 22              | 9 (40.9%)         | 3 (13.6%)    | Dr. W. M. McGrath.   |
| Claybury ...     | 75              | 23 (30.4%)        | 17 (22.7%)   | Dr. G. de M. Rudolf. |
| Colney Hatch ... | 25              | 2 (8%)            | 3 (12%)      | Dr. F. G. L. Barnes. |
| Hanwell ...      | 23              | 9 (32.1%)         | 10 (43.5%)   | Dr. G. A. Lilly.     |
| Horton ...       | 8               | 2 (25%)           | 1 (12.5%)    | Dr. W. D. Nicol.     |
| Totals ...       | 191             | 64 (33.5%)        | 40 (20.9%)   |                      |

This table includes all cases who have been sufficiently well to be sent to their homes, transfers to other institutions are not included.

On comparing Table II with Table I it will be observed that the percentage of remissions is much greater in the treated than in the untreated cases. One-third of treated, unselected cases would appear to be the maximum number of good remissions that can be expected with malarial therapy. Gerstmann, in Austria, reports that of 400 treated cases who were watched for at least two years after treatment 33 per cent. underwent good remissions and 14.25 per cent. remained stationary or showed incomplete remissions. Nonno, in Germany, reporting on 450 treated cases, also found that about one-third of the patients were able to return to their occupations. If patients with only short histories of general paralysis are treated a higher percentage of remissions is obtained, as shown in Table III, which deals with the first 63 cases treated at Claybury

Mental Hospital. All cases were clinically advanced types, and were sufficiently severe to be legally certified as insane and to require detention.

TABLE III.—Relation of Duration of Dementia Paralytica to Prognosis.

| Duration of Disease before Treatment. | Number Treated. | Number Discharged. |
|---------------------------------------|-----------------|--------------------|
| Two to eighteen months ...            | 33              | 23 (69.7%)         |
| Nineteen to over thirty months ...    | 25              | 2 (8.0%)           |

### Salvarsan Treatment.

Wagner-Jauregg, the originator of malarial therapy, advises that salvarsan be given following the course of febrile paroxysms, but several writers have stated that equally good results have been obtained without the use of this preparation. With the object of endeavouring to determine whether it is advisable to follow the malaria with salvarsan Table IV has been constructed from the cases in Table II. In order to avoid the personal element as far as possible only those hospitals at which cases have been treated both with and without salvarsan are included. The total quantity of neosalvarsan given to each patient invariably exceeded 2 grams, the greatest quantity being given to the cases at Hanwell Mental Hospital, each patient receiving 3.6 grams.

TABLE IV.—Comparison of Malarial Treatment, with and without Salvarsan.

| Mental Hospital. | Malaria alone.  |                    |              | Malaria + Salvarsan. |                    |              |
|------------------|-----------------|--------------------|--------------|----------------------|--------------------|--------------|
|                  | Number Treated. | Number Discharged. | Number Died. | Number Treated.      | Number Discharged. | Number Died. |
| Cane Hill        | 5               | 2 (40%)            | 2 (40%)      | 17                   | 7 (41.2%)          | 1 (5.9%)     |
| Claybury         | 61              | 23 (37.7%)         | 17 (27.9%)   | 12                   | 5 (41.7%)          | 0            |
| Hanwell...       | 21              | 6 (28.7%)          | 9 (42.8%)    | 7                    | 3 (42.9%)          | 1 (14.3%)    |
| Totals...        | 87              | 31 (35.6%)         | 28 (32.2%)   | 36                   | 15 (41.7%)         | 2 (5.5%)     |

The difference in the death rate of patients unfit for discharge in the two series of cases is very striking, but there is little difference in the discharge rate.

Dattner reports that in Wagner-Jauregg's clinic 50 per cent. of the cases treated with malaria and salvarsan have been able to return to their occupations, whereas only 25 per cent. of cases treated with malaria alone have been able to do so. In Horton and Bexley Mental Hospitals malaria alone was used. In Colney Hatch Mental Hospital malaria and salvarsan were invariably combined.

### Summary.

Malarial therapy produces a greater number of remissions and a smaller death rate than occurs in untreated cases. Complete remissions occur in about one-third of the cases in a mixed series, but in a much greater proportion if only cases with histories of dementia paralytica of less than eighteen months are treated.

The addition of neosalvarsan to the febrile treatment decreases the death rate amongst the cases unfit for discharge, and perhaps increases the number of complete remissions that occur.

All the medical officers are agreed that in a majority of the cases treated by malarial therapy which proved to be unfit for discharge a marked improvement in general well-being, cleanliness, and conduct was observed.

The medical officers contributing to this report are Dr. D. R. Alexander, Bexley Mental Hospital; Dr. F. G. L. Barnes, Colney Hatch Mental Hospital; Dr. J. Brander, Bexley Mental Hospital; Dr. G. A. Lilly, Hanwell Mental Hospital; Dr. W. M. McGrath, Cane Hill Mental Hospital; Dr. W. D. Nicol, Horton Mental Hospital; Dr. G. de M. Rudolf, Claybury Mental Hospital.

## COOMBE LYING-IN HOSPITAL, DUBLIN, 1826-1926.

A CENTENARY is sometimes more than a chronological excuse for congratulation, and the celebrations in Dublin during the third week in September point to something even more notable than the triumph of the Coombe Lying-in Hospital over the difficulties of 100 years. An important transformation of outlook has occurred since two poor women, dying in the snow, were responsible for the birth of a great life-saving institution. The comparative helplessness of medical science in 1826 has gradually given way to an increasing power to prevent, as well as to cure, disease, while the present-day impatience with the slow progress in the reduction of maternal mortality implies an approaching improvement in this respect also. The philanthropy which brought the Coombe Lying-in Hospital into existence has now been reinforced by the knowledge and skill so largely due to the patient research and educational work in such institutions throughout the world, and thus it is eminently fitting that a congress in Dublin, under the presidency of Sir William Smyly, should attract eminent visitors from the United States, France, Austria, Sweden, and Germany to indicate the lines of future progress.

### *History of the Coombe Hospital.*

In a previous reference on September 11th (p. 499) to the centenary celebrations we referred briefly to the dramatic circumstances attending the origin of the Coombe Lying-in Hospital, which was opened by Dr. John Kirby in 1826, with the assistance of Dr. Richard Reed Gregory, who became its first Master, in 1829. Gregory's early work was consolidated by the second Master, Dr. Thomas McKeever (1832-1835). It is interesting to recall that the hospital drew its first support from an institution for medical education, and that the educational side of its curative work has never been overlooked in the years that followed. It is therefore fitting that the importance of education should have been assigned a prominent part in the programme of the centenary celebrations. Competition with the rival school at the Rotunda Hospital was at first acute, and even bitter, but after 1838 it was realized that there was need and room for both; public recognition followed, and in 1854 the annual sum of £200 was granted by Parliament for the assistance of the Coombe Hospital, which contribution has been received regularly since then.

The hospital was granted a Royal Charter in 1867, by which its regulations were confirmed and the certificates issued to its students were recognized as valid. The generosity of Benjamin Guinness, Lord Mayor of Dublin in 1851, and later of his son, Sir Arthur Guinness, enabled building operations on a large scale to be undertaken to meet the demand for increased accommodation. Although architectural difficulties and disasters delayed the completion of the work for many years the new hospital was eventually opened in 1877, too late, unfortunately, for the joint Masters, Drs. John Ringland (1841-1876) and James Hewitt Sawyer (1845-1875), who had toiled unsparingly through times of great difficulty and depression, to share in the joy of final achievement which opened a new and happier era in the history of the hospital. Their successor, Dr. George Hugh Kidd, who had been appointed Assistant Master to the hospital in 1847, and assistant obstetric surgeon in 1868, held the post of Master from 1876 to 1883; like his predecessors, his obstetrical and gynaecological skill was based on a wide general medical knowledge, and the breadth of his outlook contributed appreciably to his success as Master. The Coombe Hospital from his time has gained steadily increasing fame, both as a hospital and a teaching centre, and in the September issue of the *Irish Journal of Medical Science* Dr. T. P. C. Kirkpatrick, Registrar of the Royal College of Physicians in Ireland, describes in detail the steps by which the hospital has climbed to its present eminence.

### *Present-day Problems.*

The annual report of the hospital for 1925, which is published also in our contemporary, shows that 1,934 admissions were recorded, an increase of 186 as compared with the previous year. The Master, Dr. Louis Cassidy, states that the percentage maternal death rate was 0.85,

and the number of morbidity cases 42, representing a percentage of 4.5, or an average of 1 in 22 cases. This figure shows a large reduction as compared with the return for the previous year. In 24 cases of morbidity commencing during the puerperium no vaginal examinations were made, no perineal lacerations occurred, and no surgical intervention was employed. Dr. Cassidy suggests, therefore, that some very interesting questions are thus raised, and in particular, attention is invited to the possibility of puerperal sepsis being attributable to lowered bactericidal properties of the maternal serum before the onset of labour. It is announced that investigations are proceeding with a view to clearing up this particular problem.

### *Centenary Celebrations.*

On September 14th an inaugural reception was held in the Royal College of Surgeons by the governors of the Coombe Hospital, and on the following evening Alderman J. Hubbard Clark, chairman of the board of governors, gave a celebration dinner. The toast of the hospital was proposed by Professor Munro Kerr of Glasgow and acknowledged by the Master of the Coombe Hospital. The other toasts were "Prosperity to Ireland," proposed by Mr. Andrew Fullerton, C.B., C.M.G., President of the Royal College of Surgeons in Ireland, and "The visiting gynaecologists," proposed by Mr. W. Doolin, editor of the *Irish Journal of Medical Science*; to the latter toast Mr. Comyns Berkeley of London, Professor J. P. Faure of Paris, and Professor P. Werner of Vienna responded. A special performance of *Juno and the Paycock* was given by the Abbey Theatre Company on September 16th; and the distinguished poet, Mr. W. B. Yeats, director of the Abbey Theatre, in welcoming the visitors, explained that it had seemed only right to select a play which dealt with the life of the poorer residents of Dublin, for whose benefit the work of the Coombe Hospital was being carried on. Since nearly half the audience had been students of the Coombe and Rotunda Hospitals, and were thus very familiar with the conditions of life portrayed in the play presented, its choice was very much appreciated. Other social festivities included a visit to the Coombe Hospital, a garden party, and a polo match.

### *The International Congress.*

The attractive nature of the scientific side of the centenary celebrations was clearly shown by the average daily attendance, which remained at about 200 until the end. The educational value of the cinematograph was emphasized practically by Professor J. P. Faure of Paris, who showed a film dealing with abdominal hysterectomy, and by Professor A. Couvelaire of Paris, who illustrated the low form of Caesarean section. Professor Essen Möller of Lund read a paper on the teaching of obstetrics in Sweden, and the conditions elsewhere were described by Professor A. Couvelaire (Paris), Professor Munro Kerr (Glasgow), Professor J. B. de Lee (Chicago), Professor Fletcher Shaw (Manchester), and Mr. Comyns Berkeley and Mr. J. S. Fairbairn (London). Mr. Eardley Holland (London) read a paper on the unnecessary induction of labour. Professor Munro Kerr of Glasgow opened a discussion, on the second day of the congress, on the lower uterine segment Caesarean section operation, and Professor Hinselmann of Altona, on the third day, introduced a discussion on eclampsia by suggesting that from the clinical point of view this disease was due to a kind of angiospasm of the peripheral circulation. Other subjects dealt with included the treatment of climacteric haemorrhages, by Professor Werner of Vienna, and the cause of menstrual pain, by Professor Beckwith Whitehouse of Birmingham. Professor A. Donald of Manchester gave a short account of the history of antiseptics and asepsis in obstetrics; Professor Louise McIlroy discussed the value of x-ray examinations in pregnancy; and Professor de Lee of Chicago raised the question whether parturition in modern civilization was not to be considered a pathological rather than a natural process. The success of the whole congress was largely due to its secretary, the Master of the Coombe Hospital.

It is announced that the proceedings of the congress will be published in book form as a supplement to the *Irish Journal of Medical Science*, and the volume is expected to appear before the end of November.

SATURDAY, OCTOBER 2ND, 1926.

## FACTORS LEADING TO THE NORMAL TERMINATION OF PREGNANCY.

EXPERIMENTS continue to be made for the purpose of determining the reason why at a particular point of time normal pregnancy terminates. In the *Journal of Physiology* (1924) there was a paper by Dr. W. H. Dixon and Mr. F. H. A. Marshall (reader in agricultural physiology at Cambridge) on the influence of the ovary on pituitary secretion as a probable factor in parturition. A further communication by these two authors to the Section of Therapeutics and Pharmacology of the Royal Society of Medicine was reported in the *BRITISH MEDICAL JOURNAL* of November 21st, 1925 (p. 947). They came to the conclusion that in the absence of fully formed corpora lutea the secretion of the ovary had a specific effect in stimulating pituitary secretion; but that when corpora lutea were present ovarian secretion had no effect on the pituitary gland. Consequently they were of opinion that during pregnancy the dominating influence of the corpora lutea hindered pituitary effect on the uterine muscle, whether by neutralizing or by inhibiting normal ovarian secretion was not clear. When the corpus luteum began to involute the uterus showed increased irritability, and with the re-establishment of normal ovarian endocrine mechanism the ovarian secretion, working through the pituitary gland, became an important factor in bringing about labour. Experiments by Dr. Dixon had already shown that normal ovarian secretion, unlike extracts of testis, epididymis, pancreas, and corpus luteum, had an exciting effect upon the secretory activity of the pituitary gland, but that this action, and the uterine contraction promoted by it, were inhibited during pregnancy, probably by the corpus luteum. The experiments in which Mr. Marshall took part showed that ovarian extract was without any direct specific action on the uterus; that in the presence of fully formed corpora lutea the pituitary gland ceased to be activated by ovarian secretion; but that at the close of pregnancy, when the corpora lutea were in an advanced stage of involution, the normal secretory activity was once more produced, and the pituitary was excited to secrete in greater quantity. When the threshold stimulus of the pituitary secretion upon the uterus was reached and passed labour pains set in. It was not suggested that the ovario-pituitary endocrine mechanism was the sole factor in producing labour, but some further exciting cause, apart from the foetus and the uterus, was needed to account for the onset of labour.

About the same time that Dixon and Marshall were conducting their experiments, Clark and Knaus had been studying the conduction of uterine contractions in the rat at different stages of the oestrus cycle. The conclusions they reached were that in the di-oestrus period there is a slow conduction between the ovarian and the middle part of the uterus, while the vaginal part contracts independently. Under the action of pituitary extract, however, all three parts of the muscle contract simultaneously, just as they do at oestrus or in early pregnancy. In comparing the two sets of observations the suggestion arose that the

changes in the behaviour of the uterine muscle are due to variation in pituitary secretion; that during pregnancy there is a steady increase in its amount; and that a sudden increase at the end of pregnancy brings about labour. It occurred to Knaus that, were this so, by injecting an appropriate quantity of pituitary gland it should be possible to induce parturition at any stage of pregnancy. It was found, however, that this was not the case.

The rabbit has a gestation period of thirty-one to thirty-two days, and for the same strain of rabbits this period is very constant. In Knaus's experiments the initial dose was that which would just cause visible uterine contractions. A continuous effect could be obtained by repeating the dose every hour for about ten doses. The investigation was begun on rabbits nearing the end of pregnancy. It was found that injection of the equivalent of 0.0075 mg. of moist posterior pituitary lobe on the thirty-second or thirty-first day of pregnancy resulted in the birth of one young rabbit within a few minutes. When the dose was repeated a few hours later a second young was born, and so on. If the dose was increased ten-fold all the young were born within ten minutes. Precautions were taken to ensure that the doe was not already in labour and that the pituitary injection was the actual cause of labour. The young were usually born before the placenta, whereas in the normal animal the foetus is born wrapped in the membranes and placenta. On the thirtieth day the dose had to be increased to 0.3 mg. to induce parturition, and the response was delayed. On the twenty-ninth day the dose had to be still further increased to 0.6 mg., and eight doses were required to bring about a response. In rabbits between the twenty-eighth and eighteenth days of pregnancy nine doses of 2 mg. were necessary, to induce a response, which was abortion of the young some days later. Investigation suggested that the cause of death was haemorrhage into the spongy, placental tissues. In rabbits between the seventeenth and first day of pregnancy no reasonable dose of pituitary had any effect on pregnancy. Amounts up to 15 mg. were used, and as the rabbit's pituitary gland weighs only 7.5 mg. this was far in excess of any quantity the animal could normally produce.

Knaus believes that his experiments show that during pregnancy there is no increase of irritability or sensitivity of the uterus, but a regular rise of contractility of the muscle. For the first three months it is said that the uterine muscle fibres increase in number, but after that there is only increase in the size of the fibres and their power of contraction. The larger the muscle cell the greater its ability to shorten itself. In consequence of this the effect of pituitary extract upon the muscle increases steadily as pregnancy advances. But Knaus finds that until near the end of pregnancy the uterine muscle cells have not grown enough to break down the tissues of the spongy layer of the placenta, even when they are stimulated by pituitary secretion. Near the end of pregnancy the muscle cells have grown so large that their maximum contraction, when caused by pituitary extract, will result in delivery. At full term the contractility of the enlarged muscle fibres is such that their spontaneous contractions alone finally cause birth, and no sudden influence or stimulus need be postulated. The contractions of labour are to be regarded as the final stage in an expanding series of events. In fact, according to Knaus, the actual process of birth is merely an affair of the uterine muscle. The growth of the muscle is due to a hormone influence, and, so far as present knowledge

goes, the corpus luteum is to be regarded as the main factor in causing this growth.

It will be seen that the two sets of experiments taken together have not cleared up the point at issue—namely, why normal pregnancy terminates. Knaus's experiments seem to indicate that normal labour is terminated by spontaneous contraction of muscle fibres which have reached a certain size; but that during the last third of pregnancy in rabbits labour can be brought on by the administration of pituitrin. The earlier in the last third of pregnancy that labour is produced the larger must be the dose of pituitrin. We are by no means clear what importance is to be attached to the pituitary secretion during pregnancy as a means whereby the three portions of the uterus are kept simultaneously contracted. But Knaus's conclusions seem to be in conflict with those of Dixon and Marshall, for their statement is that during pregnancy the secretion coming from the corpus luteum neutralizes or inhibits the ovarian secretion, which otherwise activates the pituitary gland. In both papers the authors admit certain difficulties that can be raised against their conclusions; in neither do the explanations given of these difficulties appear quite satisfactory. Thus Dixon and Marshall say that their theory does not account for abortion; they seek to attribute abortion to some extraneous cause, such as disease, drugs, or fright. They have difficulty also with cases in which pregnancy has continued after removal of the ovaries in the later stages. For this they invoke a hypothetical "compensatory mechanism." Finally, it may be asked, what prolongs the existence of the corpus luteum, and how does this body inhibit the ovario-pituitary endocrine mechanism? Knaus has been met with the objection that loosening of the placenta is indispensable for delivery. To this he has a valid reply in the fact that, while the rabbit under normal conditions casts the ovum whole, fetuses and membranes together, when pituitary extract is used the young can be cast without their membranes and placentas. Therefore, he says, the actual process of birth is merely a matter of uterine contractions. Knaus meets the suggestion that the size of the foetus is an important factor in starting parturition by recalling that the duration of human pregnancy remains constant with great variations in the size of the foetus, or with enormous extension of the uterus in cases of twins or hydramnios.

From these papers we gather that in Knaus's view the contraction-producing power of the pituitary gland, so far as labour is concerned, is merely an accidental coincidence, while to Dixon and Marshall this power is the actual cause of the onset of labour pains. In either case we are a long way from an answer to the problem why labour begins at a certain point in pregnancy.

### THE ANTIRACHITIC VITAMIN.

It is twenty years since Hopkins first suggested that rickets might be due to a deficiency of some accessory food factor, but it was not until 1918 that Mellanby brought forward definite evidence that rickets could be produced by a deficiency of fat-soluble vitamins. The history of the advance of knowledge during the past eight years is a good example of how an apparently simple problem may turn out to be unexpectedly complex. Paton and his co-workers at once disputed Mellanby's conclusions, because they found that confinement in the dark could produce rickets on a diet which was fully adequate for animals enjoying an open-air life. The question whether rickets was due to

deficient diet or to bad housing conditions was, of course, of immense practical importance.

The supporters of the deficiency hypothesis very soon found themselves in difficulties, because it was discovered that animals might develop rickets on diets containing an adequate quantity of the fat-soluble growth-promoting vitamin, and that whereas cod-liver oil would supply an adequate amount of growth-promoting vitamin and also cure rickets, yet green vegetables would produce the first effect but had a very uncertain curative effect on rickets. These difficulties were solved in a few years by two fundamental discoveries. The first discovery was that there were two fat-soluble vitamins—namely, vitamin A, the growth-promoting vitamin, and vitamin D, the antirachitic vitamin. The second discovery was that vitamin D could be produced by the exposure of food or by the exposure of an animal itself to sunlight or to any other source of ultra-violet light, whilst vitamin A could not be produced in this manner. Independent workers in America and England showed almost simultaneously that vitamin D could be produced by exposure of pure cholesterol to ultra-violet light, and researches are now proceeding with the aim of obtaining chemically pure vitamin D. For example, Rosenheim and Webster<sup>1</sup> have obtained from irradiated cholesterol a fraction, of which a daily dose of 1/100 mg. prevents rickets in rats.

Deficient diet and lack of sunlight have therefore both been proved to be causes of rickets. Both the administration of cod-liver oil, which is the richest known natural source of vitamin D, and also exposure to sunlight or ultra-violet light, have been proved to be certain cures or preventives of the disease. It is, however, extremely important to know the relative importance of dietary deficiency and lack of sunlight in the production of rickets in children. Luce<sup>2</sup> investigated the content of vitamins A and D in cow's milk, and concluded that the vitamin A content was due entirely to the nature of the cow's food. She found that the vitamin A content of milk was rich when the cow was fed on fresh green food, but was poor when the cow was on winter feed of cereals and roots, and that the vitamin A content was the same when the cow was exposed to sunlight as it was in a cow kept in a dark stall provided that the feeding was the same. Luce also concluded that the vitamin D content was chiefly dependent on the diet. Since these experiments were done it has been shown that the technique employed was not entirely satisfactory, because a lack of vitamin D can cause arrest of growth in young rats as well as occurrence of rickets, and hence to determine the vitamin A content accurately it is necessary to supply the test animal with vitamin D. This can easily be done by giving a vegetable oil that has been irradiated with ultra-violet light. This supplies vitamin D but no vitamin A. Chick and Roscoe<sup>3</sup> have repeated Luce's experiments with various refinements of technique, and their results confirm the conclusion that the vitamin A content of cow's milk is determined entirely by the nature of the cow's food, but prove, on the other hand, that the vitamin D content depends chiefly or entirely on the degree of exposure of the cow to sunlight. A cow kept in a dark stall yielded a milk poor in vitamin D, even when fed on fresh grass. The cow, therefore, does not manufacture any vitamin A, but simply passes into the milk such supplies as she has received in the food. On the other hand, the vitamin D in

<sup>1</sup> Rosenheim and Webster: *Biochem. Journ.*, 20, 577, 1926.

<sup>2</sup> Luce: *Ibid.*, 18, 715, 1924.

<sup>3</sup> Chick and Roscoe: *Ibid.*, 20, 632, 1926.

the cow's milk is chiefly manufactured in the animal's body, and the quantities of this vitamin taken in normal food are not sufficient to produce a milk rich in vitamin D. Doubtless if the cow had been treated with cod-liver oil, and thus given an excess of vitamin D in the food, a milk rich in vitamin D could have been produced.

The practical importance of this conclusion is very great, for, as the authors point out, a large proportion of the cows that provide the milk of our urban population are stall-fed, and their milk must be assumed to be deficient in the antirachitic factor throughout the year. Moreover, these conclusions can be extended to nursing mothers, and it seems to follow that the milk taken by a breast-fed child will be deficient in the antirachitic factor unless the mother either gets a reasonable amount of exposure to sunlight or is given cod-liver oil. Children living in our smoke-covered cities must therefore receive very little vitamin D in their milk throughout the winter, even when they are breast-fed. This deficiency will be compensated for if the child itself gets a reasonable amount of exposure to sunlight, or if the child is given cod-liver oil.

The evidence as to the relative importance of diet or sunlight in the prevention of rickets has fluctuated from one side to the other during the past eight years; but these experiments definitely support the view that sunlight is the more important factor, since they suggest that in a cow in the open air on a normal fresh feed the quantity of antirachitic factor actually produced by the cow is greater than the quantity taken in the food. As regards the prevention or cure of rickets, the administration of cod-liver oil would appear to be the simplest remedy. Exposure to ultraviolet radiations is probably a still more active remedy, but is expensive to organize on a large scale. These experiments confirm the view that the incidence of rickets could be greatly reduced by the prevention of smoke and the improvement of housing in our cities, but these are remedies that involve a considerable reorganization of our social system.

#### TAILED CHILDREN AND TAILED RACES.

AMONGST the specimens added to the museum of the Royal College of Surgeons of England during the present year is a very good example of a human tail. It was removed by a surgeon from a child a few weeks after birth, and measures fully four inches in length. It is covered by skin, and contains striped muscular fibres embedded in fibrous tissue, but, as is usual in such cases, vertebrae and joints are absent. Such structures represent the persistence of the external tail which projects from the caudal end of every human embryo during the fifth and sixth weeks of development, but which should undergo retrograde changes in the seventh week and disappear in the eighth, the post-anal dimple being the only trace left in normal children. Occasionally retrogression fails, and the tail increases in length and in thickness with the growth of the body, and forms the structure which surgeons are called on to remove from newly born children. In a case recorded by Dr. Ross Harrison, the inventor of the modern technique of tissue culture, the child used its tail as a medium of expression when put to its mother's breast. Human tails containing vertebrae are rare, but the soft vermiform variety are not so uncommon as is usually thought. At a recent meeting of the Royal Anthropological Institute, when the specimen now added to the Hunterian Museum was exhibited, two medical men who took part in the discussion which followed the exhibition each said that they had seen several cases. As a rule

those who possess such a structure take some pains to keep their knowledge to themselves. From time immemorial accounts have been brought to Europe of tailed races of men who had their existence in various and distant parts of the world. Usually they were said to exist in the Far East, the Philippine Islands being often alleged to be their home, or they were said to live in some inaccessible region of Central Africa. Lately excellent photographs of a tailed man were submitted to anatomists in London; the photographs are said to have been taken from a native of a small island at the southern end of the Philippine archipelago. These photographs have been accepted as genuine by competent anthropologists, and were regarded by them as rehabilitating the old myth that there were tailed families in the Philippines. It so happened that these photographs reached Dr. W. W. Keen, the Nestor of American surgeons, when he was writing a book on evolution for the better education of Daytonites. He naturally did not question the authenticity of the photographs, and included them in his book. Afterwards he discovered, as he has just explained to the readers of *Science*, that the photographs had been faked, the tail having been added by a clever photographer who apparently had some knowledge of the form assumed by a tail when it appears as an appendage to the human body. Dr. Keen, pursuing the straight, honest course of a lifetime which has now passed its eighty-ninth milestone, immediately stopped the sale of his book, and substituted for the faked photographs two authentic illustrations taken from medical literature. Dr. Keen may take some consolation from the fact that the photographer had succeeded in taking in several of our leading anatomists, but, mercifully for them, no use had been made of the photographs. The incident has a moral. In spiritualistic circles photographic evidence is relied on to prove the occurrence of phenomena, and is accepted implicitly as authentic evidence by leading spiritualists such as Sir Arthur Conan Doyle. The scientific man, when making his inquiries, has to guard against self-deception, but has seldom or never to think of wilful deception on the part of others. The highly successful man of science is therefore ill suited to take part in any inquiry where fraud, conscious or unconscious, has to be guarded against, and it is clear from the present instance that photographic evidence has to be accepted with the utmost caution.

#### THOMAS ADDISON.

Our issue of June 26th last contained an account of a commemoration at Lanercost of Thomas Addison (1795-1860) by the Border Counties Branch of the British Medical Association, at which addresses were given by several authorities, including Sir William Hale-White, who has now published in the July number of the *Guy's Hospital Reports* a full and interesting life of Addison, thus admirably completing his pious biographies of the three almost contemporary medical heroes, Bright, Hodgkin, and Addison, of the famous Borough hospital. His latest essay bears evidence of critical research into several points, such as the date of Addison's birth, which is shown to have been almost certainly 1795, not 1793 as stated in the *Dictionary of National Biography*, his entry at Guy's in 1817—not, as elsewhere stated, in 1820—and the question of priority of the recognition of true keloid, which Addison discovered for himself unconscious of a previous worker's observation. Intended for the legal profession, Thomas Addison went to Edinburgh as a medical student, and while there did not show any evidence of his future eminence, and was not, as has indeed been asserted, president of the Royal Medical Society. Coming to London, he was first house-surgeon to the Lock Hospital, then pupil and later physician, in

<sup>1</sup> Hale-White, W.: *Guy's Hosp. Rep.*, 1926, lxxvi, 253-273.

all for eight years, to the General Dispensary in Hatton Garden, where he learnt dermatology from Bateman, the successor of the great Willan. Elected assistant physician to Guy's in 1824 and physician in 1837, he resigned in 1860, moving from Berkeley Square to Brighton, where the end came on June 29th of the same year. So outstanding was his position as a teacher that a deputation of students begged him to withdraw his resignation, but "he, poor man, knowing that he had a threatening disease of the brain, was compelled to persist." Addison, as portrayed by Sir William Hale-White, was a strong, dogmatic, and at the same time retiring man, and his position at Guy's—where his personal power was much superior to that ever wielded by Bright, and equal to, if not greater than, that of Sir Astley Cooper—contrasted with his standing in the outside world, both medical and lay. At the Royal College of Physicians, where he had to wait nineteen years before being made a Fellow, he was never censor, nor did he hold any lectureship or office. When he died neither the *British Medical Journal* nor the *Lancet* published an obituary notice. No Court appointment or honorary degrees were conferred on him; and, most surprising perhaps of all, the Royal Medical and Chirurgical Society refused to publish some of his papers, even after he had been its president (1849-50). It is hard, and indeed sad, to realize that none of his discoveries brought him fame during his life; these, such as the suprarenal and blood diseases called after him, the morbid anatomy of pneumonia, the clinical signs of a fatty liver, the mixed infective character of the lesions in pulmonary tuberculosis, and the description of vitiligoidea, later more generally known as xanthelasma and now as xanthoma, are carefully annotated by Sir William, who, in addition, has collected much information about Addison's family, and reproduces photographs of their houses and a facsimile of his handwriting.

#### A POST-GRADUATE OPHTHALMIC COURSE.

Dr. A. HILL GRIFFITH, formerly lecturer in ophthalmology at the Victoria University, Manchester, and ophthalmic surgeon to the Royal Infirmary and to the Royal Eye Hospital, has sent us notes of a post-graduate class which he started in 1886 and carried on for twenty-five years. The proposal was highly approved by the late Alderman P. Goldschmidt, chairman of the board of management of the Royal Eye Hospital; and Dr. David Little, Dr. Griffith's senior colleague, placed the patients of his large clinic at the disposal of the class. Twenty-five medical men attended the first course, which consisted of twelve weekly demonstrations. The board of management of the hospital fitted up a complete system of lights; and Dr. Griffith took care that each member of the class had a light and a patient to himself, so that loss of interest and consequent general conversation might be avoided. The object kept in view was to eliminate all that could be got from textbooks, and to confine the class strictly to practical matters. The post-graduates were asked first to use the ophthalmoscope mirror alone, at a distance of 2 ft., and to note the red fundus reflex and the presence or absence of any opacities. They were trained in guiding the mirror by throwing the light on the palm of the left hand, carrying the hand in front of the patient's eye, and then withdrawing it. Dr. Griffith then explained how several opacities situated on the antero-posterior axis of the eye could be brought into view by directing the patient to look down a little, the opacities in front of the centre of rotation then moving downwards, and those behind moving upwards; although what appeared to take place was that the opacity on the anterior capsule of the lens remained stationary, those in front of this point moving downwards and all behind appearing to move upwards. The reason given was that the red fundus reflex at the level of the

pupil was taken as the point of observation. The class was instructed next in the use of the lens alone, focal illumination. Those who had a fair knowledge of the use both of mirror and lens were not taken through this elementary instruction, but were set at once to the examination of patients. When the post-graduate was sufficiently instructed he was shown cases of opacities in various situations, examples of persistent pupillary membrane, incipient senile cataract, lamellar cataract, persistent hyaloid artery, old-standing detachment of the retina, and, whenever possible, sarcoma of the choroid or glioma of the retina. Even if a man never got a proper view of the disc, said Dr. Griffith, he had learned a great deal, and was satisfied that he was getting "better and better every day." Dr. Griffith never showed those beautiful, highly finished, coloured drawings of the fundus; they were useless for the beginner. The student was next taught how to take the field of vision by means of his fingers or a piece of paper on the end of a pen, a well marked case of homonymous hemianopsia being used. A registering perimeter was never employed. Cases of bitemporal hemianopsia, central scotoma in retrobulbar neuritis, and central colour scotoma in tobacco amblyopia were then shown. The shadow test was demonstrated, and Dr. Griffith notes the difficulty he had with one man who always differed from him as to the direction of the shadow, until it was discovered that he was using a plane mirror. The next step was to test simple hypermetropia, myopia, and presbyopia, with a demonstration that subjective tests sufficed even for astigmatism with adults of average intelligence, and that only in children was a mydriatic necessary. Dr. Griffith sympathizes with those pupils who had difficulty in getting a proper view of the disc by the inverted image; but he thinks that the indirect method should be used as well as the direct in every case. The entries for the class on "The use of the ophthalmoscope and estimation of refraction" became so numerous that two classes had to be held each year. For many years also Dr. Griffith gave a summer course on "External diseases of the eye." Each patient was demonstrated before a semicircle of students. They were shown that redness of the eye might imply not merely conjunctivitis, but also iritis or corneal ulcer or a foreign body or some deeper affection; and that conjunctivitis itself might be due to chronic dacryocystitis. At each meeting one or more of the rarer diseases were shown in order to arrest the students' attention. Dr. Griffith notes that there was always one man in a class—he felt lucky if there was only one—who would rather talk and ask abstruse questions than try to follow directions. Generally he was an over-read man; the abstruse questions were put, apparently, to impress the teacher and the other members of the class. Dr. Griffith's method of dealing with this person was to tell him he would like to go into the matter fully with him—after the class. In the meanwhile he sat the man down at a lamp, if possible at a distance from the other students, and told him to report, after the class had gone, all that he could make out.

#### SET DEBATES.

THE medical symposium, or organized discussion of a single topic from various aspects, seems to be gaining favour. Concurrently the independent paper, followed by a few haphazard comments and compliments, is going rather out of fashion; though there will, of course, always be room for the individual record of new work and new ideas, as well as for the showing of good cases and specimens, which, while often wearisome to read about afterwards, are profitable to examine on the spot. This tendency towards prearranged joint discussions is, we think, a good one. It has been gathering strength for some years in the scientific Sections in the Annual Meetings of the British

Medical Association, and was a conspicuous feature at Nottingham last July. On such occasions general practitioner and specialist get closer together. The set debate has become also during recent times a fairly regular item in the diary cards of the larger metropolitan societies. The main ingredients for success are a good topic, well chosen speakers, and a capable chairman; as an adjutant the circulation beforehand of abstracts often helps to keep the proceedings in focus. At the end of last session a conference of the presidents of the various Sections of the Royal Society of Medicine decided to continue the holding of special discussions, and the Calendar of the Society for 1926-27 now gives a list of the subjects agreed upon; the dates will be settled later and announced in due course. One discussion, on blood-letting, is to be held by the whole Society, and ten others will be taken part in by the Sections immediately concerned. The subjects are as follows: Treatment of leprosy; treatment of chronic non-tuberculous infection of the lungs; uses and limitations of ultra-violet light therapy; value of recent methods of treatment in the late stages of ocular syphilis; relation of abnormalities of the blood pressure to diseases of the ear; trypanosomiasis in man and animals; diathermy; anti-toxin treatment of scarlet fever; anaesthetics in dental operations; oral manifestations of general disease in children. Here is a varied bill of fare, and some at least of these combined discussions at 1, Wimpole Street are likely to attract large audiences. Clinical debates, on the lines which have already proved so popular at 11, Chandos Street, will no doubt be held also during the forthcoming session of the Medical Society of London.

#### HEALTH AND THE LEAGUE OF NATIONS ASSEMBLY.

THE report on the work of the Health Organization (writes our correspondent at Geneva) was almost the last item of business to be presented to the Assembly of the League of Nations before its hurried close on September 25th. Along with other matters of equal importance it was rushed through almost without discussion, the delegates having booked their sleeping-car accommodation. The Assembly was compressed within the allotted three weeks only by having meetings which lasted beyond midnight. The task of bringing health matters before the Assembly was entrusted to M. Fernandez y Medina, the delegate of Uruguay, who spoke with particular gratification of the very close relations which had been established during the last twelve months between the various health administrations of the Far East. He stated that the Japanese Government had done a great deal to facilitate the detailed study of its excellent health administration by a group of health officers appointed by the administrations of other Far Eastern countries. It was believed that the personal contact which had been made between Japan and the health administrations of British India, Australasia, China, the Soviet Republic, the Philippines, and the Dutch East Indies would make possible a valuable system of collaboration in future in the solution of common problems. A co-ordination committee, which included representatives of the permanent Health Committee of the League and of the health administration of Japan, was engaged upon the task of drawing up monographs containing an account of recent Japanese research, so that medical men in the West would have an opportunity of becoming acquainted with Japanese progress. Another enterprise had been an interchange of medical officers in the colonial services of Senegal, Gambia, Portuguese and French Guiana, the Ivory and Gold Coasts, Togoland, Nigeria, Dahomey, and Sierra Leone. In Latin America, again, health officers had been taking part in various interchanges. One Brazilian specialist had been afforded the opportunity of investigating in Japan, for a period of nine months, the parasitic

diseases prevalent among the Japanese emigrants to Brazil. The Maharaja of Kapurthala, who represented India in the Assembly, laid stress on the part which the League could take in Asia in the struggle against plague, cholera, and other diseases, and on the value of the epidemiological intelligence bureau at Singapore, in whose work all the countries of the Far East are co-operating. The number of ports in telegraphic communication with the Singapore bureau is now above one hundred. The advisory committee of the Singapore bureau is presided over by the head of the health administration of British India, and the vice-chairmen represent the health administrations of French Indo-China, Japan, the Dutch East Indies, Siam, and China. The Health Committee of the League has already been enabled to initiate and co-ordinate investigations and research work bearing upon vaccination against malaria, the endemic distribution of that disease, and the measures to be taken to prevent the risk of an outbreak of epidemic pulmonary plague in Manchuria. The Assembly passed a resolution recording its gratification at the work accomplished, and referred certain proposals for enlargement of the work to the Health Committee for consideration.

#### THE STEGOMYIA IN GIBRALTAR.

THE chief feature of the report on the health of Gibraltar in 1925<sup>1</sup> is an appendix of thirty-five pages containing an account of a mosquito campaign undertaken during the summer of that year. The common mosquito of the colony is the *Stegomyia fasciata*, and there are no anophelines. It is remembered that there were serious epidemics of yellow fever there in 1804, 1813, and 1828, and the authorities observe that the opening of the Panama Canal brings the colony into direct communication with countries where yellow fever has been endemic. It is, however, pointed out that the conditions now are very different from what they were a hundred years ago, for the United States administration of the canal zone may be relied on to prevent infection being transmitted by way of the canal. In any case, until rainwater underground tanks, of which there are a vast number connected with the houses in Gibraltar, are abolished completely, it seems hopeless to expect that the *Stegomyia* will cease to flourish. Some comfort may be obtained from the measures described in the report, but they seem scarcely necessary because of any fear of yellow fever. There are several annexes to this appendix; they contain much useful and practical information, and models for the framing of regulations and for propaganda purposes. The report itself shows no falling off in the high standard which has been maintained for many years, notwithstanding the overcrowded state of the occupied area and the exceptionally large percentage of families living in one-room dwellings. The population, apart from the garrison, is stationary, and has been so ever since an official record has been kept. In 1925 it was 17,268; but 1,500 British subjects and 5,000 Spaniards entered the colony daily from the neighbouring Spanish town, La Linea. The birth rate, which was 23 per 1,000 of the fixed civil population, has varied but little during the last ten years. The death rate—14.8 per 1,000—also shows little variation, except during the influenza years towards the end of and immediately after the war. The infantile mortality—83.3 per 1,000 births—is lower than in 1924, when it was 91.6 per 1,000. The death rate from acute infectious diseases was 0.62 per 1,000 of population, and from pulmonary tuberculosis 1.7 per 1,000. Influenza and pneumonia together accounted for 1,022 of the 1,262 cases of notifiable disease; but influenza, of which 900 cases were notified, was removed from the list

<sup>1</sup> Annual Report on the Health of Gibraltar for the year 1925. By Lieut.-Colonel W. G. Smiles, D.S.O., R.A.M.C. Gibraltar: Garrison Library. (8vo, pp. ix + 72 and 35 pp. of appendix.)

of notifiable diseases in November of the year under review. There was no other outbreak of disease of any importance, but seventeen persons were subjected to antirabic treatment on account of bites from dogs or cats suffering from, or suspected of, rabies. The report, as a whole, is well prepared and arranged, and records, as in previous years, the facts connected with various infectious diseases, with general sanitary work, and the activities of institutions for maternity and child welfare and care of the tuberculous. There are also several statistical tables, charts, and a sanitary map of Gibraltar.

#### ANTIMALARIAL MEASURES.

Of the various enterprises usefully carried on under the auspices of the Rockefeller Foundation, none excels in practical value the work of the International Health Board in the study and control of malaria. In Palestine during 1924, as narrated in the annual report of the Foundation for that year, surveys were made which show that while the mosquito *Anopheles bifurcatus*, breeding in wells and cisterns, is the carrier of malaria in towns, the principal vector in rural areas is *Anopheles clutis*. In the towns much benefit has been derived from oiling the wells and cisterns: in the country districts hopes are fixed on prospective legislation requiring the tenants of land to check the breeding of mosquitos. Palestine, it is suggested, at the present time needs management of its water supplies rather than general drainage. Other regions, on the other hand, have been greatly the better for the draining of superfluous water. In the malarious parts of Porto Rico, for example, the disease is worst near cane fields where drainage is neglected: Fajardo, where drainage is efficient, appears to be free of infection. Promising results have been got in Brazil by antilarval measures alone without quinization of the inhabitants, and in Nicaragua an important gold-mine, which had been closed for some years owing to the high malaria rate among its labourers, has, after drainage, been reopened. Officers of the International Board, in response to an invitation received from the Government of Italy, made a general survey of the malaria position in that country. Control, especially in the South of Italy, has hitherto been largely confined to the free distribution of quinine, but now the Government provides in addition screened houses for its own employees, and offers premiums to private employers who follow its example. In order to throw light on the malaria problems of the southern United States, a special investigation has been made at Leesburg in Georgia. Of the three indigenous Georgian anophelines, it has been ascertained that *Anopheles quadrimaculatus* is for practical purposes the sole vector of malaria. It frequents level lands and impounded water. The imago when at rest does not assume the traditional anopheline posture, with its body elevated at an angle of 45 degrees: it adopts, on the contrary, a flat or culicine attitude. Its range of flight was observed to be small; few specimens travelled a mile from their breeding place. The larvae of Georgian mosquitos during the winter months, when the temperature of the water ranges from 39° to 50°, spend most of their time at the bottom of pools. These studies and inquiries, made in various lands and under various conditions, exhibit the diverse character of the questions involved in the repression of malaria. The methods which help one district may be inapplicable to another. The habits of one mosquito may protect it from assaults which are lethal to allied species. Thus a Georgian larva at the bottom of the water is beyond the usual range of surface oiling. Without patient research there can be no clear understanding of the several problems and no sure guidance as to appropriate action. The report of the Rockefeller Foundation is at once a stimulus and a caution to all engaged in antimalarial campaigns.

#### AUTOPSY OF A "FAMILIAR."

In a leading article on "A Harveian tercentenary," on August 14th last, we remarked that William Harvey in 1634 was appointed to examine four women known as the Lancashire witches. On September 18th we published an interesting letter from Dr. H. A. Clowes, in which the story of Harvey's association with Sergeant-Surgeon Clowes and others in the examination of the women was told in greater detail. This letter was made the subject of a humorous little leading article on "Harvey and the witches" in the *Times* of September 21st. This brought a letter from Dr. Letitia Fairfield, published in the *Times* two days later, quoting an account of another investigation into alleged sorcery which was made by Harvey. The story is told in Professor Notestein's *History of Witchcraft in England*, and is based on a letter in the *Gentleman's Magazine*, 1832, Part I, 405-410. It appears that about 1685 a justice of the peace in south-west England, whose name is unknown, wrote a letter in which he said that he once asked Harvey his opinion on witchcraft: Harvey replied that he believed there was no such thing, and related a story of a visit he made to a reputed witch when he was at Newmarket with King Charles I. The woman lived in a lonely house on the borders of the heath. Harvey told her that he was a wizard, and had come to converse with her on their common trade. The woman believed him, because, as Harvey said, "You know I have a very magical face." Harvey asked to see the witch's familiar; whereupon the woman brought out a dish of milk, made a chuckling noise, and a toad came out from under a chest and drank some of the milk. The witch was persuaded to go out to get some ale half a mile away; and while she was absent Harvey cut up the toad and found the milk inside. He came to the conclusion that the animal "no ways differed from other toades," but that the old woman, having tamed it, had come to believe it a spirit and her familiar. On her return the old woman "flew like a Tigris" at Harvey, and would not be pacified with money; so that Harvey was obliged to tell her that he was the King's physician, sent to discover if she were a witch, and in case she were to have her apprehended. Dr. Fairfield thinks that this is "the only scientific examination on record of that unique and mysterious feature of English witchcraft, the 'domestic familiar'"; and she agrees with Professor Notestein that the episode may have influenced Harvey in favour of the Lancashire women.

#### MEDICAL RESEARCH COUNCIL.

ORDERS of the Committee of Privy Council have been issued by which Dr. Charles J. Martin, F.R.S. (Director of the Lister Institute and Professor of Experimental Pathology in the University of London), and Sir Frederick Gowland Hopkins, D.Sc., M.B., F.R.S. (Professor of Biochemistry in the University of Cambridge), are appointed members of the Medical Research Council into the vacancies caused respectively by the death of the late Lieut.-General Sir William Leishman, F.R.S., and by the retirement of Professor T. R. Elliott, F.R.S.

THE Royal Society of Medicine will hold a reception at 1, Wimpole Street, W.1, on Monday, October 18th. At 8.30 p.m. Fellows and their guests will be received by the President, Sir James Berry, and Lady Berry. At 9.30 Sir Arthur Keith, M.D., F.R.S., will give a short address entitled "John Bull: a study in anthropology," with lantern illustrations. The library will be open, and various objects of interest will be exhibited. Music and light refreshments will be provided.

## England and Wales.

### THE CARE OF WELSH CRIPPLES.

SCHEMES for the systematic care and cure of cripples have of late years been put into operation in one county or group of counties after another; and it was not likely that Wales would long bear the reproach of lagging behind, especially when there was such a shining example at its very doors as that afforded by Shropshire—the pioneer in the movement. Following on a lecture delivered by Sir Robert Jones in July last to the representatives of the authorities which are responsible for the care of cripples in Wales, a movement has been started under influential leadership to provide the necessary organization by the inauguration of a Welsh branch of the Central Committee for the Care of Cripples, having its headquarters at the Prince of Wales' Hospital, Cardiff. The secretary of this hospital, Mr. Gilbert D. Shepherd, points out the great importance of recognizing the fact that the county councils, county borough councils, local education and other authorities which are responsible for instituting and maintaining work are the proper bodies for the scheme. Sir John Lynn-Thomas has consented to act as honorary organizer, and Dame Agnes Hunt has agreed to render all assistance in her power in the organizing of the after-care clinics. As tuberculous cripples over the whole of Wales and Monmouthshire are already being dealt with by the Welsh National Memorial Association, it will only be necessary to provide for the needs of the non-tuberculous cases. This circumstance reduces the scope of the scheme, but nevertheless the benefits of open-air treatment for children are desirable for all and an open-air hospital is needed. This, it is felt, should be large enough to allow of cases being retained until their cure is complete or until efficient after-care is forthcoming. The needs of the adult cripple can be dealt with by the Prince of Wales' Hospital and by the Shropshire Orthopaedic Hospital. For the present it is considered that these hospitals—one of which, it is to be noted, is not in Wales—will suffice, but the question of the establishment of an open-air hospital in Wales will have to be dealt with ultimately. At present the most urgent task is the provision of the after-care clinics in Wales, recapitulating the objects of the Central Committee for the Care of Cripples, and urges the desirability of co-operation with existing agencies, especially the Welsh National Memorial, and an advisory board is to be formed to settle matters of administration and sites for clinics, on which the Welsh Board of Health, medical officers of health, the consulting staff of the Prince of Wales' Hospital, and others will be represented. It is suggested that a lecture campaign on the care of cripples shall be carried on through Wales. The scheme starts with the advantage of the support of the Prince of Wales' Hospital at Cardiff and of its influential council and staff, and difficult as the present situation is, on account of the coal strike, we feel sure that the patriotism of the Welsh people will see to it that it is carried through.

### LORD MAYOR TRELOAR CRIPPLES' HOSPITAL.

During the year ending March 31st, 1926, the Lord Mayor Treloar Cripples' Hospital at Alton extended its work to include general orthopaedic cases, which had previously only been admitted exceptionally. One observation ward and two ordinary wards, containing in all forty beds, have now been set apart for non-tuberculous crippled children. In September, 1925, a new massage and medical gymnastic department was opened. Other extensions during the year include the enlargement of the nurses' home at a cost of £10,125, and the completion of the new isolation hospital. The whole hospital now contains 350 beds, and there is accommodation for the technical training of crippled lads from 14 to 18 in the college. The income during the year showed a "record" increase in annual subscriptions, and in spite of the expense of the new light department the

weekly cost per patient decreased by 1s. 3d., as compared with the previous year. In his annual report the medical superintendent, Sir Henry Gauvain, refers to the treatment of lupus vulgaris by intensive local light, associated with general light baths, which he has found most successful, though it is lengthy, difficult, and costly. Artificial light proved effective also in open tuberculous wounds, sinuses, and multiple lesions.

### VOLUNTARY HOSPITALS IN SHEFFIELD.

A report of the work in 1925 of the voluntary hospitals in Sheffield has been issued by the City of Sheffield Local Voluntary Hospitals Committee, which was formed in 1921; its previous reports were incorporated in the publications of the Sheffield Voluntary Hospitals Advisory Council. Tables are provided of the income and expenditure under various heads of the Sheffield Royal Infirmary, the Sheffield Royal Hospital, the Jessop Hospital for Women, and the Children's Hospital, during 1925, and the totals are compared with those of the four previous years. Another table, by means of an aggregate balance sheet for each hospital in 1925, shows that a surplus was realized in each case, and supports the committee's recommendation of the maintenance of the voluntary system in hospital administration at all costs. Statistical tables are included of the number of patients treated, the work of the Sheffield Hospitals Council, and miscellaneous information about the number of patients contributing towards their maintenance, admitted free, and supporting the penny-in-the-pound scheme. It is stated that extension of the work of the committee is contemplated to include the surrounding areas from which the Sheffield hospitals draw a large percentage of their patients, and that negotiations are in progress with the boards of the county and cottage hospitals and the general practitioners concerned, with the view of utilizing the available beds in the district to their fullest extent.

### CARE OF MENTALLY DEFECTIVE CHILDREN IN GLAMORGAN.

A proposal to purchase Hensol Castle, Glamorganshire, for the treatment of mentally defective children has been approved by the Glamorganshire Education Committee. It is intended to provide in the whole scheme a residential school at Hensol Castle for the care of mental defectives, with provision for special classes in existing schools or schools in the county, and special day schools in the more thickly populated areas for backward children. In this way the residential school will be kept for children who cannot benefit from education elsewhere. The cost of the purchase is estimated at between £30,000 and £40,000; the estate covers 1,082 acres, of which 500 would be used for the purpose of a colony in connexion with the residential school. After the children have been educated in the residential school they will subsequently form the population of the colony, where suitable occupation can be provided for them, and their parents will be able to visit them from time to time. At present such children are being sent so far away as Lancashire, Yorkshire, and London.

## Scotland.

### SCOTTISH MEMORIAL TO DAVID LIVINGSTONE.

DAVID LIVINGSTONE was born in 1813, in a house on the banks of the Clyde, at Blantyre, near Glasgow. He was admitted a licentiate of the Faculty of Physicians and Surgeons of Glasgow in 1840. His early home has now fallen into considerable disrepair, and is threatened with demolition. An influential committee has therefore been formed to purchase the house and grounds, and to restore them as a national memorial in which personal relics of Livingstone may be preserved, as has been possible in the case of Scott and Burns. An appeal is now issued for £12,000, of which it is believed £7,000 will be required for securing the property, making extensive repairs and internal adjustments, and enclosing and laying out the

grounds, while an endowment of at least £5,000 is considered necessary for maintenance. In connexion with this appeal an illustrated pamphlet has been issued, which may be obtained from the organizing secretary, Mr. J. G. Harley, 36, Chalmers Street, Edinburgh. Subscriptions should be sent to Mr. J. Macgregor Hart, the honorary treasurer, 142, St. Vincent Street, Glasgow. Livingstone died at Chitambo on May 1st, 1873. His remains were brought home and the burial in Westminster Abbey was on April 18th, 1874.

#### GLASGOW SLUM CLEARANCE.

A Board of Health inquiry has been sitting during the past week to investigate the question of slum areas which the Glasgow Corporation propose to clear, and also to investigate an improved housing scheme which has been approved by the corporation. The corporation desires to clear away some 1,000 houses and to erect accommodation, chiefly of the nature of tenements, in other parts of the city. The previous slum clearance scheme introduced in 1923 involved 2,000 slum dwellings, and is now almost complete. Mr. Archibald Crawford, K.C., on behalf of the corporation, explained that the scheme related to five of the public health areas of the city, in some instances clearance of a considerable congested district, and in other cases of isolated houses here and there. The medical officer had chosen what he regarded as the worst dwellings to be cleared out. The number of persons to be displaced was 4,532, and this scheme was a second instalment of a series of slum clearances which the city had in view. Within recent years the corporation had determined upon slum clearances which would involve about 50,000 persons, or between 13,000 and 14,000 houses. Many of the properties were houses of a past age, in a dilapidated state; they had a very unhealthy effect, and were productive of early death, particularly among children. Dr. A. S. M. McGregor, medical officer of health for the city of Glasgow, giving evidence as to conditions prevailing in the slum areas, said that for some years prior to 1909 a survey had been made of the city, from the slum area point of view, and at that time 13,000 houses had been placed in the category of insanitary dwellings. Examples were given by Dr. McGregor to show the crowded character of the slum areas in the Water Street district of the northern area; 633 inhabitants lived in 48 houses in an area of 1.5 acre; this meant 433 persons to the acre, as compared with 57 for the city generally. The death rate was 25 per 1,000, compared with the general city death rate of 14; and the infantile mortality was 148, as compared with 107 for the city. In an area about Adelphi and Crown Streets the population was 943 to the acre, the death rate 42, and infantile mortality very high; and the death rate from respiratory causes was 10.1, as compared with 2.7 for the city generally. In contrast to this, 271 new houses were to be erected at Germiston, in the north-eastern district, with a density of 17 houses to the acre; in the east end at Duke Street 130, with a density of 28 houses per acre; 180 new houses at McNeil Street, with a density of 33.5 houses to the acre; and 288 new houses at Govanhill, with a density of 31.3 houses to the acre. All these houses would be well lighted and ventilated, and would consist of two and three apartments. Mr. A. C. McMillan, city chamberlain, in giving evidence, said that the outlay required further for the slum clearance involved an expenditure of about £500,000, or a loss of £17,000 for the next sixty years; half of this sum, however, was to be paid by the Government, so that £8,500 per annum would be the share of the Glasgow corporation. Mr. John Bryce, director of housing, spoke of the new schemes. The sites, he said, were within easy reach of the places where the persons to be displaced were now living. The reason for differences in density of population was that in the older districts streets were already formed, while in districts now to be laid out for the first time, like Germiston, the streets were to be planned as seemed best, and this was being done in a generous manner, while good health conditions would be kept in view. In forming plans the principle now followed was to build 50 per cent. of two-room houses and 50 per cent. of three-room apartment houses.

#### SCOTTISH ASYLUMS' PATHOLOGICAL SCHEME.

The twenty-ninth annual report of the Board of the Scottish Asylums' Pathological Scheme contains an account by the pathologist, Dr. F. E. Reynolds, of his research and routine work during 1925. In collaboration with Dr. Logan Turner, Dr. Reynolds has made a special study of the paths of infection to the brain, meninges, and venous blood sinuses from neighbouring peripheral foci of inflammation. Two reports have been published in the *Journal of Laryngology and Otology* for February and July of the present year; it is proposed to publish a third report towards the end of the year. In addition to routine pathological investigations performed in the laboratory in Edinburgh, visits are being paid to various mental hospitals with a view to assisting pathological investigations, and a course of demonstrations and lectures for the diploma in psychiatry was given in the first quarter of 1926. Post-graduate teaching in pathology has also been carried on, and lectures and demonstrations have been delivered to undergraduates studying pathology in Edinburgh. A collection is being made of pathological and microscopical preparations for teaching purposes, and these are available for use by medical superintendents of the mental hospitals contributing to the scheme. Dr. Reynolds is anxious to obtain material for demonstrating degenerative changes in the central nervous system, especially in cases of tabes dorsalis, disseminated sclerosis, and hemiplegia.

#### CALEDONIAN MEDICAL SOCIETY.

The annual meeting of the Caledonian Medical Society was held at Storrs Hall Hotel, Windermere, on September 24th. The president, Dr. W. E. Henderson, medical officer of health for Westmorland, delivered an address on "The historical and literary associations of Westmorland" to a large audience. Sir Robert Jones, Bt., K.B.E., F.R.C.S., and Sir Samuel Scott, Bt., High Sheriff of Westmorland, were elected honorary members. The annual dinner was held in the evening. The 1927 meeting will take place in Dundee under the presidency of Dr. Angus McGillivray, and in 1928 the society will celebrate its jubilee at Edinburgh under the joint presidency of its founders, Dr. S. Rutherford Macphail and Dr. W. MacNaughton.

## Ireland.

#### TREATMENT OF TUBERCULOSIS IN THE FREE STATE.

IMPORTANT questions relating to public health were discussed at the summer meeting of the National Association of Insurance Committees. It was stated that on the question of the treatment by Insurance Committees of tuberculous insured persons in excess of the number contracted for under agreements with local authorities, a deputation was received by Dr. Stephenson, chief medical officer of the Department of Local Government and Public Health. The deputation pointed out that the insufficiency of the sanatorium benefit fund was largely caused by widespread non-compliance with the Act, and that it was the duty of the Government to make arrangements for meeting its moral obligations to the insured persons who had complied with the Act. Dr. Stephenson admitted that the position created a hardship for insured contributors, and said that his department was concerned with safeguarding the ratepayers. If the deputation could put their views in the form of a memorandum he would place it before the Minister. It was suggested that a letter of protest should be sent to the Commission, and that it should be requested to negotiate with the Government with a view to ensuring that adequate funds were made available for the treatment of sanatorium applicants throughout the Saorstát. Dr. King explained the report of the medical committee for Dublin County, which was adopted. It dealt with a more rigid form of notification and disinfection, power to compel removals of tuberculous patients, suitable homes to segregate advanced patients, medical inspection of school children, inquiry into milk supply, overcrowded dwellings, profiteering

Correspondence.

OCT. 2, 1926]

in the necessities of life, medical benefit as an aid to early diagnosis, after-care committees, contributions for patients, and graduated work as an adjunct to treatment.

TUBERCULOSIS IN BELFAST.

Reporting on the work during 1925 of the tuberculosis department of the county borough of Belfast, Dr. Andrew Trimble, the chief tuberculosis officer, states that there has been a reduction of the death rate due to pulmonary tuberculosis in Belfast of 30 per cent. in the last ten years, 55 in the last twenty years, and 60 in the last thirty years. He refers to the vexed question of the effects of tuberculosis on pregnancy and vice versa, and concludes that this disease cannot be convicted of contributing in any marked degree to interruption of the normal course of pregnancy. He finds that if a tuberculous woman is not in an advanced stage of the disease, or acutely ill, is well nourished and living in hygienic surroundings, pregnancy may be little apparent effect on the clinical course. On the other hand, in advanced stages of tuberculosis, pregnancy has an acute type of tuberculosis. He emphasizes the attended with very serious results. He has frequently found that value of x rays in the diagnosis and prognosis of pulmonary and osseous tuberculosis. He has frequently found that, even when a sinus has appeared to be firmly healed for months, or even years, the x-ray film may still show much rarefaction of the diseased bone, indicating the need for further rest and treatment. With regard to the diagnostic importance of the albumin test in sputum, he states that out of 850 sputums examined for albumin and no albumen, 14 were found to contain tubercle bacilli gave also a positive test for albumin. He adds that even if a negative albumin reaction is of uncertain value as indicating the absence of pulmonary tuberculosis, a positive examination provides a valuable indication for the repeated examination of the sputum for tubercle bacilli. Dr. Trimble gives a short account of the visit of the medical commission from Belfast last year to Paris, Geneva, Frankfurt, Hamburg, and Copenhagen to investigate Continental methods of treating tuberculosis. We referred to the report of this commission on August 8th, 1925 (p. 270). Dr. Trimble also gives a report on the work of the Belfast committee which has been investigating the value of sanocrysin, and concludes that, while the method seems to represent a distinct therapeutical advance in definitely selected cases, yet further observation for at least a year of the results obtained will be necessary in order to estimate the degree of permanence.

FERMANAGH ASYLUM, TYRONE.

The resident medical superintendent (Dr. Patrick) of Tyrone and Fermanagh Asylum in the course of his annual report states that on January 1st, 1925, there were 429 males and 347 females in the institution; 95 males and 74 females were admitted during the year, and 97 males and 76 females discharged. There appeared to be little difference in the forms of mental disorder and their relative proportions during recent years. A considerable number of mania entered the institution. The number of cases of mania was 42, and of melancholia 71. As in previous years, a considerable number of the newly admitted patients were in poor health, suffering from malnutrition from one cause or another, which necessitated hospital treatment. In 73 cases there were only two cases in which over-indulgence in alcohol was given as the principal, and in 5 it appeared as a contributory cause. This suggests that the inhabitants of Tyrone and Fermanagh are very temperate, or that alcohol is not so potent a cause as a sign of insanity as has been urged by some reformers. The view that over-indulgence is to be regarded more as a sign of nervous instability than as a cause for mental breakdown seems to Dr. Patrick to be the more correct. In any case, he adds, the reforms so vehemently advocated would materially lessen the number of admissions to that institution, where the experience of a considerable number of years was contrary to the belief that alcohol was one of the most powerful of the causes of insanity.

CHOLECYSTOGRAPHY.

SM.—The opinion expressed at Nottingham that cholecystography should become a standard method of investigation is not only the opinion of Professor Graham, who devised the test, but of the leading radiologists in America, Germany, France, and this country, who have tested and proved its value in several thousands of cases.

At the Queen's and St. Chad's Hospitals, Birmingham, we have made over 120 cholecystographic investigations, and the diagnoses given have proved correct at operation in over 90 per cent. of the cases.

In a very large proportion of the patients not the slightest toxic reaction was experienced. A few patients have complained of nausea, sickness, and headache. In only ten patients has the reaction been of the severity of the "bilious attacks" previously experienced by the patients, and only two in our series had the symptoms of severe surgical shock. The skin of one of these was of a pale yellow tint before the injection; throughout the day after receiving the injection the skin became deeper in colour. Her gall bladder was normal in shape, position, and density. It was filled and emptied in the normal time.

A number of patients have had very marked jaundice due to complete obstruction of the common bile duct; none of these had a reaction which was noticeable. Age apparently does not influence reaction, as many of our patients were over 60 years of age. The type of patient who gets a severe reaction is the patient who has had what we believe to be a toxic haemolytic jaundice, as the gall bladders of such patients fill and empty normally.

The dye used in all these tests is sodium tetraiodophenolphthalein made by the British Drug Houses and Kodak Limited. The technique advised by Graham is strictly adhered to on all occasions. The percentage of accurate diagnoses and the percentage of patients who had the reaction in our series are very similar to those recorded by the Mayo Clinic and other large clinics in America and Germany.

Naturally we shall all welcome a dye which is absolutely non-toxic. In the meantime we, personally, will be reluctant to abandon a method of investigation which is proving of immense use in the diagnosis of diseases of the bile passages, at any rate until we have full details of the single fatal case recorded so briefly by Mr. Raison in your issue of September 18th (p. 542).—We are, etc.,

JAMES F. BRALLSFORD.  
A. W. NUTTALL.

Birmingham, Sept. 24th.

THE ABDOMINAL CRISES OF PERNICIOUS ANAEMIA.

SM.—Mr. Hamilton Bailey's article in your issue of September 25th (p. 554) illustrates very forcibly the truth that now and again severe abdominal pain may find its interpretation in the existence of pernicious anaemia. The lesson has been read before, but as such experiences appear to be unusual its restatement is more than justified. In one of his well known studies of pernicious anaemia Dr. William Hunter speaks both of "acute gastric discomfort" and of "attacks of tearing, gripping pain in the intestine," and in a case recorded by Dr. J. George Taylor the description runs of abdominal pain which "came on rather suddenly, lasted for several hours, and appeared to cause intense agony."

Some years ago I was asked to see a patient who was said to be the victim of recurring attacks of abdominal pain for which no explanation had been found, even though under their provocation the abdomen had been opened by a very experienced surgeon. The case was undoubtedly one of pernicious anaemia, as established in the end by post-mortem examination. A point of particular interest in this experience is that the diagnosis was very near at hand when once an ophthalmoscopic examination was made. There, plainly enough, were retinal haemorrhages, and necessarily a blood examination followed.

Mr. Hamilton Bailey usefully points out that the chance of mistaking the gastric crises of tabes dorsalis for an acute abdomen has been reduced to a minimum by routine examination of the pupils and the tendon jerks. Equally, let routine practice extend to the examination of the fundus oculi, and the confusion against which he now warns us would be in the highest degree improbable, for few indeed are the cases in which pernicious anaemia is not marked by the presence of retinal haemorrhages. Mr. Bailey tells us of one patient operated on for "perforated gastric ulcer," and of another in whom "a diagnosis of gall-stone colic was made." Yet the true interpretation in each case was pernicious anaemia. Personally I should entertain a very strong suspicion that the ophthalmoscope would have avoided conclusions which led to the operating theatre in the one instance and to its very threshold in the other.—I am, etc.,

London, W.J., Sept. 25th.

C. O. HAWTHORNE.

### GOITRE IN CHILDHOOD.

SIR,—In your issue of September 25th (p. 577) Dr. Milligan states: "The theory put forward by Dr. Turton, that excess of lime has something to do with goitre prevalence, may be correct, and Sir James Berry (BRITISH MEDICAL JOURNAL of December 5th, 1925, p. 1060) has supported this view . . ." To state it thus is putting the cart before the horse, and I desire, Sir, to disclaim, for my own part, any priority for the view which Dr. Milligan attributes to me. The reverse order is the correct one, but the statement of Dr. Milligan is not quite correct. If he will turn to the *Lancet* (February 6th, 1926, p. 269) he will find that Sir James Berry, in his lucid article on "Some clinical aspects of simple goitre with remarks on its causation," actually said:

"To my mind, there is abundant evidence that the cause of endemic goitre is to be found in drinking water, and though I fully admit that the actual nature of the poison is not definitely proved, I am inclined to think that in the minute particles of inorganic mineral matter (probably calcareous), suspended in the water, we find, even if not the actual poison, at any rate an essential accompanying factor."

And further, in his concluding remarks, he said:

"There is much evidence that practically all waters which produce goitre contain frequently, although not necessarily at all times and seasons, mineral matter in suspension, usually in an extremely fine state of subdivision."

That is very different from attributing the goitre-producing properties of a water to those mineral salts in solution which constitute either permanent or temporary hardness. In no part of his article does Sir James attribute the cause of goitre to hardness of water supplies. Calcium, whether present as carbonate or sulphate, is not the only substance which makes waters hard. Magnesia and iron contribute, and neither of these has been implicated either by Sir James Berry or myself, nor do I see in his article any impeachment of calcium sulphate.

Conclusions drawn as to the hardness of water supplies and the percentage incidences of goitre are faulty if no account be taken of these facts, though Dr. Milligan falls into the error of attributing to us the view that it is the hardness of a water which determines the amount of goitre.

The water supply of the Heanor Urban District is, at its source, clear and sparkling. It is softened by Clark's process, and at the consumer's end the water is frequently turbid, the turbidity varying from a slight milkiness to occasionally resembling a bismuth mixture. This turbidity is due to the presence of particles of calcium carbonate, in a very fine state of subdivision. After softening the water is run into settling tanks and carbonated. A portion of the softened and carbonated water is filtered. At the present time there are not nearly enough filters to deal with the total volume of water consumed.

The latest analysis of the raw water shows that the temporary hardness is 18.16, and the permanent 15.42. The appearance in the 2-foot tube was clear and bluish. After softening and carbonating the temporary hardness was reduced to 8.15 and the permanent to 9.71, and after softening and filtering the respective hardnesses were 2.15 and 8.14. The total hardness was thus 10.3, but the results of analysis showed that in the softened and filtered water calcium carbonate amounted to 2.10,

calcium hydrate to 1.11, and magnesium carbonate to 4.6 parts per 100,000. In appearance the softened water was turbid and opaque by reason of the presence of white suspended matter consisting mainly of  $\text{CaCO}_3$ . The appearance of the softened and carbonated water was turbid and yellowish, whilst the appearance of the filtered water was clear.

Yet this district is one which has been a seat of endemic goitre for many years, but although the disease exists to a considerable extent at the present day, its endemicity is not so severe as in former years, prior to the introduction of the present water supply. I have published elsewhere statistics of goitre, both in children and adults. Goitre is still endemic in this district, and in all probability the reason for its existence is the present state of the water. A typical example of a well water used for drinking purposes in this district in 1906 revealed the following: Total solids 140.6, free ammonia 0.045, albuminoid ammonia 0.050, chlorine 19.8, nitrogen as nitrates and nitrites 1.0 per 100,000 parts. This is a grossly polluted drinking water. There are no records available to show whether at any time, though it is probable enough, the well waters used for drinking were turbid from inorganic matter in suspension. They were in all cases surface wells, sometimes in clay, more often in a calcareous sandstone, locally termed "ratchel."

I agree entirely with Dr. Milligan that the whole question of the etiology of endemic goitre needs further inquiry; it appears reasonably certain that the condition is by no means to be explained as a simple iodine deficiency. Much of the work hitherto done in that respect is faulty and unreliable. I recently had sent to me a specimen of virgin soil from Tacna in Chile. It was a light brown sandy soil. I sent it to a firm of manufacturing and analytical chemists for the determination of its iodine content. They examined it repeatedly by the method of Hercus, Benson, and Carter<sup>2</sup> in the exact manner as described by them. No iodine whatever could be detected, but on re-examination by a different method, much more accurate for determining minute quantities of iodine, 8 parts of iodine per 10,000,000 parts of soil were found to be present. The method used by Hercus, Benson, and Carter is both cumbersome and inaccurate, and the conclusions drawn by them as to the cause of endemic goitre in New Zealand, based on their examination of soils for iodine content by that method, are totally unreliable.—I am, etc.,

Heanor, Derbyshire, Sept. 25th.

PHILIP H. J. TUNTON.

### TREATMENT OF VARICOSE VEINS BY INJECTION.

SIR,—In the *JOURNAL* for September 25th (p. 554) you publish a short article by Dr. A. H. Douthwaite on the treatment of varicose veins by injection, and since, as he points out, this method is not much practised in England, I am emboldened to record my limited experience on these lines.

Dr. Douthwaite employed in his series the method suggested and practised by Genévrier, who for this purpose made use of various salts of quinine, notably the hydrochloride, to produce a local thrombosis.

Whilst in Paris, during the early part of 1925, I made use of this method on several occasions with considerable success, although the patients, unlike those of Dr. Douthwaite, almost invariably complained of considerable pain following the injections. Later, however, Professor Sicard kindly instructed me in the technique of the method suggested by himself and Professor Paraf.

I immediately adopted this in preference to the older system, since the patients, with one exception, preferred it on the score of its greater freedom from pain; whilst the sodium salicylate solution employed would appear to be less toxic than quinine.

An account of this method was recently published by Sir Sidney Alexander,<sup>3</sup> who stated that he had employed it in a hundred cases with uniform success. A point which he did not, however, emphasize is that it is unwise to

<sup>1</sup> *Journ. Royal Sanitary Institute*, Vol. xvi, No. 12, 1925.

<sup>2</sup> *Journ. of Hygiene*, 1925.

<sup>3</sup> *Lancet*, July 25th, 1925.

CORRESPONDENCE.

OCT. 2, 1926]

inject more than 5 c.cm. of the 40 per cent. solution at a time, although as much as 10 c.cm. of the weaker dilution may be given initially, if it be thought desirable. It is an advantage to make the injections in a sitting position, owing to the temporary giddiness which often follows. I never saw a recurrence during nine months.

As Dr. Douthwaite points out, the disability produced by varicose veins is so enormous that any method which can be employed safely and without interfering with the occupation of the sufferer is entitled to consideration.—

I am, etc.,

W. S. C. COPEMAN, M.B., M.R.C.P.

London, W., Sept. 25th.

SIR,—With reference to my article in the JOURNAL of September 25th (p. 554) may I encroach on your space to answer certain recurring questions in the numerous letters I have received?

1. The object of applying the tourniquet is to keep the veins distended even when the leg is raised rather than to delay the passage of the quinine-urethane solution into the general circulation. Alternatively the patient may sit on the edge of the couch with the legs hanging down; veins on the posterior aspect are then, however, inaccessible. Without the aid of a tourniquet for dealing with such sites the patient must stand on a table, or else the operator must grovel on the floor.
2. It is, as a rule, unnecessary to inject veins higher than the middle of the thigh, because above this they rarely produce symptoms. I have, however, been as high as the saphenous opening without untoward result. Herein lies the great advantage of the quinine solution over the salicylate follow sodium by other workers. I have seen a thrombosis follow sodium salicylate treatment, which ascended with alarming rapidity, and had to be controlled by two weeks' immobilization. This does not occur with quinine.
3. The persistent ulcers of faulty salicylate injections do not occur if quinine solution enters the subcutaneous tissue.
4. Rest in bed is not required after artificial thrombosis, because it is not associated with infection and the clot is, therefore, not friable.
5. The injections should obviously be made from below upwards to prevent interference with the next puncture by blood.

—I am, etc.,

Worthing, Sept. 27th.

A. H. DOUTHWAITE, M.D.Lond.

SIR,—The article by Dr. A. H. Douthwaite on the treatment of varicose veins by injection suggests the cure of a very common ailment by means well within the scope of the general practitioner, and looks on the face of it well worth his serious attention.

May I point out one simple omission from his note, which may or may not be of importance? Dr. Douthwaite, after describing his process, makes no mention of the length of time the tourniquet should remain in position after the injections have been given, and as thrombosis is the natural cure it might be helpful to know how long the tourniquet should remain above the injected parts.—I am, etc.,

BENJAMIN WAINMAN, M.R.C.S.Eng.,  
L.R.C.P.Lond.

Leeds, Sept. 27th.

THE PERIOD OF INFECTIVITY OF WHOOPING-COUGH.

SIR,—Two years' experience as resident medical superintendent at a large hospital for children in London encourages me to answer Dr. Devereux's question (September 18th, p. 542).

If a child has had whooping-cough for six weeks it is non-infectious. The first "whoop" does not occur for several days after the onset of the disease, and it is during this time that infection of others most often occurs. There is no question whatever that many patients will occasionally "whoop" for months and, rarely, years after an attack, but in this stage they are clinically non-infectious.

I doubt if the bacteriological evidence is sufficiently strong to pronounce dogmatically on the subject, but experience suggests that six weeks from the onset is probably erring on the side of over-caution, and is hence a perfectly safe time limit to adopt.—I am, etc.,

London, Sept. 23rd.

ERIC I. LLOYD.

MINER'S NYSTAGMUS.

SIR,—I have read with interest Dr. Percival's letter in the JOURNAL of July 31st (p. 224), which has just reached me. Though I quite agree with him that light has very little to do with the causation of miner's nystagmus, I must take exception to his statement that twenty-five years ago the percentage of nystagmus cases at the South Moor Colliery was notoriously high. I was surgeon to that particular colliery both before and after the time he mentions, and though I have not the actual figures before me, I can say with confidence that, of cases receiving compensation, or being "off work," the percentage due to nystagmus was practically negligible.

I am particularly interested in nystagmus, as I was resident at the Sheffield General Infirmary, and working chiefly under the late Mr. Simeon Snell at the time when he brought forward the theory that it was nearly entirely the position of the hewer when at work that caused the disease, which theory was combated by, I believe, Dr. Court of Barnsley.

I have in my possession a pamphlet in book form by Mr. Snell, which to my mind, taken together with observations made on patients attending the eye department of the Sheffield Infirmary at that time, proves position at work and consequent strain of the extrinsic muscles of the eyeball to be the chief, if not the only, outside factor in the causation of the disease.—I am, etc.,

R. E. INGRAM-JOHNSON.

Banting, Federated Malay States,  
Aug. 27th.

CONTINENTAL MEDICAL GRADUATES.

SIR,—So far as I have been able to ascertain no attempt has been made up to the present time to form a roll or association of practitioners in the United Kingdom who hold the M.D. degree of a Continental university.

Apart from the associations of Brussels and Lausanne medical graduates, which between them number nearly 450, there are about 220 graduates of other universities, so far as my present researches have revealed. The numbers are made up approximately as under: Malta 40, Germany 56, Italy 38, Switzerland 31, Holland 22, France 21, Greece 4, others 9. These men, scattered far and wide, for the most part out of touch with each other, represent such famous universities as Freiburg, Vienna, Zürich, Naples, Rome, Padua, Bologna, Florence, Berne, Zürich, Geneva, Louvain, Ghent, Liège, and Paris, and contain some of the most eminent men in the profession.

Beyond the many advantages which would accrue to graduates themselves from the formation of an association and a roll, which could be done for a very small initial subscription, there would be advantages and greater facilities arising for the rest of the profession, as, for example, information could be made more readily available with regard to post-graduate study in foreign clinics, conditions abroad, etc.

I should be very glad to hear from any medical practitioners holding Continental doctorates in medicine interested in the formation of such a roll and association, with a view to holding a meeting at an early date, and I should myself be only too glad to place at their disposal the MSS. roll which I have at present compiled.—I am, etc.,

CHARLES A. H. FRANKLIN, M.D.Laus.,  
M.B., B.S.Lond.

Bickley, Kent, Sept. 25th.

POST-GRADUATE COURSES IN CANADA.

SIR,—In a recent issue of the BRITISH MEDICAL JOURNAL you note the fact that post-graduate courses lasting about one month have been given this year at the McGill University Medical College at Montreal. The tone of the note led me to believe that you were somewhat surprised as well as gratified at the fact.

I felt that you would be interested to know that such courses, although of shorter duration, have been given at other Canadian medical schools before this year: notably at the Dalhousie University Medical School at Halifax. I believe I am correct in stating that these were first introduced in 1922 with a view to benefiting the general practitioner in the nearby towns and country who felt he could

not afford the time or money to leave his practice for a longer trip. Since then they have been held regularly and have proved highly satisfactory and most interesting.

It seems unfortunate, although inevitable to some degree, that so little should be known in the mother country regarding the higher educational centres of the various dominions.—I am, etc.,

September 10th.

E. COSMAN DAVIS, M.D., C.M.

### THE MEDICAL PROFESSION AND LIFE INSURANCE COMPANIES.

SIR,—The last paragraph of Dr. W. A. Murray's letter in the *JOURNAL* of September 25th (p. 579) is of considerable interest. For some years past I have refused life insurance work on account of the smallness of the fee.

Quite recently I received the proposal forms of a well known company with a request to examine a certain gentleman, the fee being one guinea. I returned the forms with an intimation that my fee for the work was two guineas. I received a polite letter in return from the actuary regretting that he could not pay me a larger fee, as that was the fee arranged between the British Medical Association and the life offices.

I wrote to the Medical Secretary of the British Medical Association for information on this point. He informed me that the agreement for a one-guinea fee was arrived at six years ago. "This agreement was only reached with the insurance companies after protracted negotiations, and there was a distinct danger at one time that the companies would give up medical examinations save in exceptional circumstances."

This rather surprised me. Are the insurance companies indulging in an eleemosynary act in offering a fee at all to medical practitioners?

The minimum fee adopted by the Buckinghamshire Division of the British Medical Association for a visit to a patient's house is 3s. 6d. and mileage. Buckinghamshire is an agricultural county, and the wage of the farm labourer is 31s. 6d. per week. Is it not time that wealthy clients should be made to pay a reasonable fee for a written opinion of a highly skilled nature?—I am, etc.,

Haddenham, Bucks, Sept. 25th.

T. W. S. PATERSON.

SIR,—I agree with Dr. W. A. Murray that it is time to review the relations existing between the medical profession and life insurance companies.

I have an idea that many years ago a guinea was considered to be the correct fee that one should receive from any recognized insurance company for medical examination, and when the British Medical Association agreed with insurance companies that the minimum fees should be half a guinea for cases up to and including £100, and one guinea for cases over £100, I do not think that the wholesale introduction of non-medical policies was anticipated.

Now, as some of the companies, who do an enormous business in policies in the region of £100, only use us in their doubtful cases, our insurance work is but a fraction of what it was thirty years ago, and certainly more difficult when we are dealing only with cases which the companies themselves are doubtful about. It is my opinion that in these cases the minimum fee should be raised to one guinea.—I am, etc.,

London, N., Sept. 27th.

JOHN PAXTON.

### INFLUENZA ANTIGEN IN THE TREATMENT OF ENCEPHALITIS LETHARGICA.

SIR,—I am naturally gratified that Dr. Keith (September 18th, p. 525) has had such success with my influenza antigen in the treatment of his two cases of encephalitis lethargica. These patients may fairly be taken as test cases, for they were many weeks ill and steadily degenerating when this antigen was used, and the first had had three doses of a commercial influenza antigen, the influence of which was apparently nil, while a one million dose of my antigen had an immediate result.

This emphasizes a most important point in the quality of antigens: to be effective they must be made from

recently isolated virulent microbes unspoiled by any detoxicating influence, such as overheating, in their manufacture. In the case of the influenza bacillus and such easily killed microbes no heat is necessary for killing them. Moreover, the microbes are grown on agar containing 10 per cent. of unheated defibrinated human blood, virtually a human tissue, so that as little virulence as possible is lost.

It is very difficult now to obtain influenza bacilli isolated from a case of typical influenza, or, still better, from a case of encephalitis lethargica. In the latter cases blood cultures should be made, the blood being transferred to broth at blood-heat and kept at this temperature on the way to the laboratory. In the former case the sputum must not be allowed to get cold on the way to the laboratory, and the cultures should be made on blood-agar slopes warmed to blood-heat. A thermos flask is invaluable for the conveyance of such specimens to the laboratory.

I should be much obliged to any laboratory which would supply me with an antigen isolated from such cases and made as I suggest, since cases of the kind are now few and far between in Ireland.—I am, etc.,

University College, Dublin, Sept. 21st.

W. M. CROFTON.

### APPENDICITIS AND VEGETARIANISM.

SIR,—Referring to Mr. Hamilton Bailey's letter which appeared under the above heading in your issue of September 18th, he will find abundant testimony that appendicitis (and also cancer) are of very rare occurrence in non-flesh eating peoples in the utterances of many Indian practitioners—R.A.M.C. and otherwise. Again, some little time ago I saw it recorded of a number of hospitals in Northern India that "of 50,000 in-patients treated in them for the past ten years only fourteen were cases of appendicitis." The Surgeon-General of Egypt has also pointed out (and returned) that while the percentage incidence of cancer and appendicitis among the Moslem population is <sup>considerably</sup> that of Europe, that of the Copts, who are vegetarians, is very small indeed.

I may add that I am connected with several vegetarian societies in England and know a fairly large number of their members. I have never yet known of appendicitis occurring in any who had followed a flesh-free dietary for twelve months. I therefore consider Mr. Bailey's case an exceptional one.—I am, etc.,

Torquay, Sept. 27th.

ROBERT H. PERKS, F.R.C.S. Eng.

### CANCER MORTALITY AND AGE RATES.

SIR,—Dr. E. Hudson asks (September 25th, p. 579) for evidence that cancer is more prevalent among the well-to-do than the poor. If he will refer to my "Note on cancer occurrence in Hampstead and Shoreditch," published in *Public Health* (March, 1924), he will find what he seeks.

With the kind assistance of Dr. Stevenson, superintendent of statistics, I worked out the death rates from cancer for each sex, between the ages of 45 and 65 and over 65, for the eight years 1913 to 1920. The death rates for males were almost the same in the two boroughs, but for females more than 25 per cent. higher in Hampstead than in Shoreditch. Quoting from *Public Health*:

"The men are usually the best fed members of working class families, and consequently there would not be so much difference in nutrition between men in Hampstead and Shoreditch. But smoking is recognized to be the chief cause of cancer of the mouth, and alcoholism is an important cause of cancer of the mouth, throat, and stomach (see Sir A. Pearce Gould, Bradshaw Lecture, 1910, quoting a paper by Sir Arthur Newsholme, and Annual Reports on the Health of Woolwich, 1913-18). . . . There is considerably more alcoholism in Shoreditch than in Hampstead, and there is probably at least as much smoking. This perhaps accounts for the nearly equal occurrence of cancer among men in the two boroughs."

Over the age of 65 cancer was nearly twice as prevalent in Hampstead women, and much more prevalent in Hampstead men, and it is at this age that we should expect to find most overnutrition among the well-to-do and least among the poor.—I am, etc.,

SIDNEY DAVIES,  
Late M.O.H. Woolwich.

Worthing, September 28th.

Practitioner, March, 1926

# MEDICAL NOTES IN PARLIAMENT.

THE BRITISH MEDICAL JOURNAL 617

Sm.—In reply to Dr. E. Hudson (September 25th, p. 579) I may state that the mortality rates were obtained from the Registrar-General's death returns. I had worked out the variation in the ages of the two classes. I accept the figures which Dr. Hudson has given for the towns named, and freely admit that the death rates are materially altered. I still maintain that the conditions of their labour, dietary, etc., are factors that favour less cancer, less appendicitis, less constipation, and less of the toxins that produce other ill effects. From over fifty years' experience of medical work I am confident that cancer has increased. We know the chief causal factors; much can be done by free clinics to educate the people on this question, and early diagnosis can be made of growths in the precancerous stage.

During the past thirteen years in Blackpool the majority of the patients were women; in cases of cancer of the breast they were florid, obese, and weighed too much. Only yesterday this was confirmed by one of the hospital surgeons. I may say that all the patients were in fairly good circumstances. In my early student days cancer patients were usually thin.—I am, etc.,

JOHN BROWN.

## A DISCLAIMER.

Sm.—Our attention has been drawn to a book called *Microbe Hunters*, recently published by Harcourt, Bruce and Company, New York, and alleged to have been written by one Paul de Kruif—a gentleman whose name is quite unknown to us. The work evidently aims at being a kind of popular history or rather romance regarding medical discovery, and mentions us among others. We should like an opportunity to say, for the information of your readers, that the author's statements about ourselves and our researches are almost entirely apocryphal; that they are not supported by reference to the subjects with which we have been concerned is obviously incomplete.

We have been legally advised that some of his assertions regarding ourselves are libellous according to British laws; but in America we have no means of protection except a public denial of the truth of his allegations, and we therefore trust that you will allow us to publish such a denial, as emphatically as we may, in your columns.

Dr. Cuthbert Christy's signature does not appear on this letter as he is in Africa; before sailing, however, he left us the following statement:

"With regard to Paul de Kruif's book *Microbe Hunters* I beg to emphatically state that it contains statements which are totally erroneous, misleading, and some of them libellous. As an example I will quote paragraph 2, page 264, which reads: 'The third member (viz., myself) became disgusted with the ignorance and failures of his two colleagues and went off prospecting for rubber.' This paragraph is absolutely untrue and libellous. It suffices to say that I have always given credit to the *Morning* for his discovery of the trypanosome as the etiological agent of sleeping sickness—see, for instance, my letter to the *Post*, August 22nd, 1925. As regards my abandoning my colleagues and going off prospecting for rubber, this is entirely libellous. I never abandoned my colleagues and, as a matter of fact, I did not get interested in rubber until 1906, which was three years after the labours of the First Sleeping Sickness Commission were completed."

—We are, etc.,

ALDO CASTELLANI,  
GEORGE C. LOW,  
DAVID NABARRO,  
RONALD ROSS.

September 27th.

## Obituary.

THE tragic death of Dr. L. B. PERRY on July 18th, whilst on a holiday at Mundesley, deprives the profession of one of those outstanding men who can ill be spared, and his loss will be acutely felt by a wide circle of patients and friends, both in this country and in that part of Mesopotamia where much of his time was spent. Lionel Banks Perry was born on December 31st, 1884, at Chertou Vicarage, Cambridge; his father was the Rev. S. E. Perry. From Tonbridge School he went to Queen's College, Cambridge, and after taking his B.A. degree in the Natural Sciences Tripos of 1906 he entered St. Thomas's Hospital.

In 1909 he graduated M.B., B.Ch. Cantab., and obtained the M.R.C.S. and L.R.C.P. diplomas. Whilst at St. Thomas's he served as house-physician, obstetric house-physician, casualty officer, and clinical assistant in the children's department; subsequently he was resident medical officer at the Queen's Hospital for Children. From 1913 to 1920 he was in partnership with Dr. Wilson Tyson at Lowestoft, with the appointment of assistant surgeon to the Lowestoft Hospital. During part of this time Perry held a temporary commission in the R.A.M.C., and saw service in the Near East, being invalided home in 1918 from Salonika with malaria. From 1922 to 1925 he served as surgical specialist in Mesopotamia, the first part of time being passed at Mosul, and later at Hillah. There he showed great surgical ability and earned a high reputation amongst the Arab population. The uncertainty prevailing in Iraq decided him against renewing his contract for a longer period and he returned to England. A few weeks before his death he had entered into a partnership at Royston, near Cambridge. As a colleague he was the essence of loyalty, possessed of a strong sense of duty and high ideals, having a judicial regard for the rights of others and a charm of manner which endeared him to all. His kindness of heart and sympathetic understanding made his presence welcome wherever he went. Combined with these sterling qualities as a man, Perry possessed a fine degree of professional skill and courage, and a keen appreciation of human nature. No matter whether his patient was rich or poor, English or Arab, he was accorded that great respect and affection which comes only to the true and upright man whose single purpose is the welfare of others in time of sickness. To those who were privileged to know him well his death came as a very great shock; and at a time when great happiness and much good work lay ahead.

J. M. H.

The deaths are announced of Dr. JOSEPH TRISSIER, honorary professor of the Lyons Faculty of Medicine, and Dr. E. BABAK, professor of physiology in the Masaryk University at Brno, known for his work on regulation of respiratory movements and on the influence of the endocrine glands on amphibian metamorphosis.

## Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

PARLIAMENT met on September 27th to approve the renewal of the Emergency Regulations for the month of October. The House of Lords rose the same night, but the Commons sat again on September 28th to debate the Regulations in detail. On both days speeches were delivered from the Government and Opposition Front Benches, which were meant to discover possible methods of compromising the coal dispute, but nothing appeared to be effected.

### Hours of Workers in Poor Law Institutions.

On the motion for the adjournment of the House, on September 27th, Miss Susan Lawrence made allegations as to the way in which the nominees of the Minister of Health were administering relief. She said that the first thing they did in the West Ham Union was to increase the hours of labour in the infirmary from forty-eight to fifty-six a week. The people affected were sick nurses, sick attendants, and other officials of the hospital. The Union approached the nominee Guardians, who admitted that some of the staff should be dismissed as a consequence of the increase in hours. Eleven sick-room attendants had already been dismissed, and it was anticipated that more would be dismissed. It would be bad enough if this action were taken in London infirmaries, but it was very much worse in East Ham. In London infirmaries the cancer and venereal cases were removed to the Metropolitan Asylums Board, which had a forty-eight hour week. In fixing a forty-eight hour week the Asylums Board had borne in mind the notorious fact that no kind of nursing was so great a claim on the attention or physical strength of the nurses as that of the last stages of cancer or venereal disease cases. The first-fruit of the policy of the Ministry of Health was that the dying should have less alleviation of their pain. These nurses and attendants were only human; they could not put as much work into a twelve-hour shift as they could into a shorter one. With longer hours it was impossible that the sick could be

adequately looked after. She asked if it was proposed to lay down any rules on the hours to be worked by nurses. Mr. J. J. Lawson referred to the administration of relief in the Chester-le-Street Union. He said that the Minister of Health should have sent down doctors from his own department to examine young men in order to settle whether or not they were destitute. Mr. Chamberlain said Miss Lawrence was under a misapprehension about the relations between the West Ham guardians and the Ministry. Under the recent Act of Parliament the West Ham guardians and those at Chester-le-Street were not special commissioners. They were boards of guardians, and the relations between them and the Ministry were exactly the same as with any other board. They had the same powers, and he had no more powers over them. All he could do when he had complaints, therefore, was to draw their attention to the matter and ask for their observations. That had been done in regard to the increase of hours in certain institutions in West Ham, but he had not yet received a reply from the guardians. It was quite untrue to suggest that the dismissal of these attendants was subject to his discretion.

Mr. Chamberlain, replying to Mr. W. Thorne, who asked if he was aware that the West Ham Union Poor Law Commissioners had decided to abolish the forty-eight-hour working week and the eight-hour day of a number of their employees, said that he had received certain representations on the matter and was in communication with the board of guardians.

#### *Boards of Guardians and Outdoor Relief.*

In the House of Commons on September 28th Mr. Chamberlain, replying to further questions about boards of guardians, said that it was not the duty or the practice of boards of guardians to report changes in their administration or scale of relief which they might use for their guidance, but he had been informed of reductions in scales made since May 1st in forty-two instances. He knew of no case where a board of guardians had ceased to grant any relief to the dependants of those involved in the present coal stoppage, but six boards were reported to have decided that only indoor relief should be granted in these cases. Such a decision was within the discretion of the guardians so far as regarded applications considered by them, but nothing could interfere with the duty of a relieving officer to deal as might be required with any case of sudden or urgent necessity. It was obvious that a dispute of this magnitude and duration must involve hardship and even distress. He had no reason to suppose that boards of guardians were not fully discharging their duties in the matter.

## Universities and Colleges.

### UNIVERSITY OF LONDON.

#### SEMON LECTURE.

The Semon Lecture will be given by Dr. A. Brown Kelly in the Barnes Hall of the Royal Society of Medicine, 1, Wimpole Street, W.1, on Thursday, December 2nd, at 5 p.m., the subject selected being nervous affections of the oesophagus.

#### UNIVERSITY COLLEGE.

The following appointments for the session 1926-27 have been made with the Faculty of Medical Sciences at University College:—*Demonstrators in Anatomy:* L. Reuvid, M.B., B.Ch., and E. R. P. Williams, M.B., B.Ch. *Sharpey Scholar in Physiology:* L. E. Rayliss, B.A.

## The Services.

### DEATHS IN THE SERVICES.

Brigade Surgeon Charles Edward Wikeley, R.A.M.C.(ret.), died at Blackpool on July 24th, at the great age of 93. He was born at Leeds on April 26th, 1833, and took the L.S.A. in 1854, and the M.R.C.S. in 1858. Entering the army as assistant surgeon on January 12th, 1859, he became surgeon major on April 1st, 1874, and retired, with an honorary step, on February 2nd, 1884. In the old regimental days he served as assistant surgeon in the 19th Foot, or Green Howards, also known as Alexandra Princess of Wales's Own Yorkshire Regiment.

Major Arthur Ormsby Fitzgerald, R.A.M.C.(ret.), died on July 30th, aged 64. He was born on September 26th, 1861, and after taking the L.R.C.S.I. and L.K.Q.C.P. in 1883, entered the army as surgeon on May 30th, 1885, becoming surgeon major after twelve years' service, and retiring on May 30th, 1905. He served in the Burma war in 1885-87, receiving the frontier medal with a clasp; and in South Africa in 1899-1900, when he took part in operations in Natal, including the action at Laing's Nek, the relief of Ladysmith, and the actions of Spion Kop, Van Kraai, the Tugela Heights, and Pieter's Hill, was mentioned in dispatches in the *London Gazette* of February 8th, 1901, and received the Queen's medal with four clasps.

Colonel William O'Hara, Madras Medical Service (ret.), died at Boscombe, Hants, on August 6th. He was born at Saugon, on January 30th, 1852, the son of George O'Hara, I.M.D., and educated at the Madras Medical College. After taking the L.R.C.P. and S.F.A. in 1874, he entered the L.M.S. as surgeon in September, 1874, attained the rank of colonel in May, 1906, and retired in June, 1911. His younger brother, Lieut.-Colonel A. J. O'Hara, also of the Madras Medical Service, retired in 1902, and died in 1915.

## Medical News.

THE prizes will be distributed at Charing Cross Hospital Medical School on Wednesday, October 6th, at 3.30 p.m., by Field-Marshal Sir William Robertson. The ceremony will take place in the out-patients' hall; tea and coffee will be served afterwards, and a reception will be held in the school. The annual dinner of past and present students will be held that evening at the Hotel Victoria, Northumberland Avenue, at 7.30.

THE annual dinner of past and present students of St. Mary's Hospital Medical School will be held at the Connaught Rooms, Great Queen Street, on Monday, October 4th, at 7.30 p.m. The chair will be taken by Dr. G. W. H. French.

DR. LOGAN TURNER, P.R.C.S.Ed., consulting surgeon, Ear and Throat Department, Royal Infirmary, Edinburgh, will deliver an address on "Some aspects of intracranial infection of nasal origin" at the opening of the winter session of the Central London Throat, Nose, and Ear Hospital, on Friday, October 15th, at 4 p.m.

AT the opening of the winter session 1926-27 of the University of Durham College of Medicine, Newcastle-on-Tyne, an introductory address, on the freedom of medicine, will be given by Dr. O. O. Hawthorne, F.R.C.P., in the Examination Hall of the College, on Friday, October 8th, at 4.30 p.m.

THE Lord Mayor has issued invitations to a festival dinner in support of St. Mark's Hospital, City Road, to be held at the Mansion House, London, on Tuesday, October 26th, at 7.30 p.m.

THE annual dinner of the Chelsea Clinical Society will be held at the Café Royal on Tuesday, October 26th, at 7.30 p.m.

THE opening meeting of the session 1926-27 of the Hunterian Society will take place at Simpson's Restaurant, Cheapside E.C.2, on Monday, October 18th, at 7.30 p.m. On Monday November 15th, the society will meet in the Cutlers' Hall E.C.1, at 9 p.m., when there will be a discussion on medicine and the press. At the dinner meeting at Simpson's Restaurant on Monday, December 6th, at 7.30 p.m., there will be a discussion on the nervous child.

A SHORT post-graduate course is being held at St. Mary's Hospital Medical School, Paddington, on Saturday, Sunday, and Monday, October 2nd, 3rd, and 4th. The lectures are given in the library of the Medical School and are open to all medical practitioners without fee.

THE first of the special demonstrations arranged by the Fellowship of Medicine for the winter session will be given by Mr. W. H. McMullen, on common injuries of the eye, at the Royal Westminster Ophthalmic Hospital, Charing Cross, on October 8th, at 5 p.m. This demonstration is open to all members of the medical profession, without fee. A series of lectures on emergencies in medicine and surgery will begin on October 14th, at 5 p.m., in the lecture room of the Medical Society of London, 11, Chandos Street, W. The Central London Throat, Nose, and Ear Hospital will hold a comprehensive intensive course in laryngology, rhinology, and otology from October 4th to 23rd; the clinical part of the course may be taken in conjunction with the operative or separately, but early application is requested for the latter as the entry is limited. From October 18th to 30th there will be a combined whole-day course in diseases of children, arranged by the Paddington Green Children's Hospital, the Victoria Hospital for Children, and the Children's Clinic. On October 18th also two fortnight courses begin—one in gynaecology at the Chelsea Hospital for Women, and the other in genito-urinary diseases at St. Peter's Hospital. A series of eight clinical demonstrations on tropical disease will be held twice a week at 2 p.m., beginning October 5th, at the London School of Hygiene and Tropical Medicine. Copies of all syllabuses, the general course programme of the Fellowship, and its journal may be obtained from the Secretary, 1, Wimpole Street, W.1.

THE Infants Hospital and the National Association for the Prevention of Infant Mortality and for the Welfare of Infancy have jointly arranged a course of lectures on infant care for health visitors, nurses, midwives, and superintendents of infant welfare centres. It will be given in the Lecture Hall of the Infants Hospital, Vincent Square, Westminster, S.W., on Mondays, at 6.30 p.m., from October 4th to December 6th. The association has also arranged a refresher course of lectures on child welfare for health visitors, nurses, midwives, etc., to be held at the City Hall, Cardiff, from October 2nd to 30th, inclusive. Information as to fees may be had from the honorary secretary, Miss Halford, 117, Piccadilly, W.1.

HEALTH week will be observed in numerous towns from October 3rd to 9th. The practice of devoting one week in the year to propaganda work on behalf of the prevention of disease was instituted in 1912; a central organization under the Royal Sanitary Institute was formed in 1914.

THE Home Office has issued draft regulations with reference to the weight of various materials which may be lifted by workers in factories and workshops dealing with woollen and worsted textiles. Copies of the regulations may be obtained from the Factory Department of the Home Office, and any objection to them must be sent to the Secretary of State within thirty days from September 21st.

THE following new appointments in the Tropical Division of the London School of Hygiene and Tropical Medicine are notified: Dr. V. B. Wigglesworth, to be assistant in the Department of Entomology; Dr. Leslie J. Davis, to be research student and demonstrator in the Department of Tropical Pathology and Bacteriology; and Miss Joyce Leishman, B.Sc., to be research student and demonstrator in the Department of Helminthology.

A CONGRESS arranged by the International Society of Sexology will take place in Berlin from October 11th to 15th. Information regarding the society and the congress may be obtained from Dr. Moll, Berlin W. Kurfürstendamm 45, or Dr. Stutzin, Berlin W. Kurfürstendamm 44.

A PRACTICAL and theoretical course in microbiology and immunology for public health students will be held at Amsterdam University, beginning on October 4th. Further information can be obtained from Dr. A. C. Ruys, Mauritskade 57, Amsterdam.

PROFESSOR E. W. SCRIPTURE, of the University of Vienna, announces a course for the winter semester, entitled "Introduction to speech neurology, including the theory of aphasia according to Henry Head."

THE Queen Alexandra Sanatorium Fund, which gives grants to enable tuberculous patients with limited means to receive sanatorium treatment at Davos, assisted nine patients in the summer of 1925, and twenty-six during the following winter. Before October, 1925, such patients were accommodated in a pension under the control of the fund; the new arrangement is stated in the annual report of the fund for 1925-26 to have been more satisfactory than the old, both financially and medically.

## Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **THE EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1.**

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the *JOURNAL*, should be addressed to the Financial Secretary and Business Manager.

THE TELEPHONE NUMBERS of the British Medical Association and the *British Medical Journal* are *MUSEUM* 9561, 9562, 9563, and 9564 (internal exchange, four lines).

THE TELEGRAPHIC ADDRESSES are:  
EDITOR of the *British Medical Journal*, *Aitology Westcent, London*.

FINANCIAL SECRETARY AND BUSINESS MANAGER  
(Advertisements, etc.), *Articulate Westcent, London*.

MEDICAL SECRETARY, *Mediscera Westcent, London*.

The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Barclay, Dublin*; telephone: 4757 Dublin), and of the Scottish Office, 6, Drumshigh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 4361 Central).

## QUERIES AND ANSWERS.

### MEDICAL HISTORY.

DR. L. A. PARRY (Hove) writes: I shall be grateful if any of your readers can help me with the following information: (1) Any book on the history of medical jurisprudence, especially as regards the date of the discovery of the various tests for arsenic, strychnine, etc. (2) The volume of the *Lancet* in which a letter on tooth extraction by Dr. Smethurst, the poisoner, appears. (3) Any book dealing with the methods of medical qualification three to four hundred years ago. (4) Any information of Basil Valentine the alchemist.

### ERYTHEMA NODOSUM.

DR. ARTHUR FINEGAN (Highgate) asks for suggestions regarding the etiology and treatment of the following case: A hospital nurse, aged 35, has suffered at intervals during the past twenty years from periodic attacks of unmistakable erythema nodosum.

About two onsets supervene almost every year, irrespective of season or apparent cause. She sustained attacks of both malaria and dysentery in East Africa during the war. At present there is a suspicion of left ovarian inflammation, and she runs a temperature if overtired by work. In other respects she enjoys good health.

### MUCOUS COLITIS.

"R. P." asks for suggestions in the treatment of a female patient, aged 39, who suffers from mucous colitis. The condition is of several years' duration, but lately has been more severe; there is much pain, especially at night, the pain being relieved by passage of mucus in "balls" and at times in "casts." The patient had scarlet fever about 20 years of age, followed by an otitis media, which eventually cleared up. About two and a half years ago she began to suffer great pain at her periods, menorrhagia being very marked; pil. ergotina and curettage had little or no effect. Lately hysterectomy had to be performed. At the operation there were vast adhesions all round the pelvic organs, and the uterus and ovaries were removed. The patient is now getting hormotone (one tablet thrice a day before food). After the operation the mucous colitis seemed to light up and the pain marked. The abdomen there is well marked. Rectal treatment has been tried: by saline injections in the morning, making sure of daily action of bowels; charcoal has been given in large quantities; dimol has been used without any effect. The bulky diet as advocated by the German authorities has been tried, and also the French plan of mincing all animal food and passing vegetables through a sieve. Lately the potassium permanganate and thyroid treatment has been tried, but has failed to give relief.

### WATERY EYES.

"A. G. F." writes to ask if any reader of the *BRITISH MEDICAL JOURNAL* can say what is the cause of watery eyes. For weeks and months his eyes are normal and give no trouble, then suddenly they produce a redundancy of tears, which overflow and require the constant application of his handkerchief. Is there any literature on the subject?

### ARSENIC AND TAR AND CANCER.

DR. VINCENT MOXEY writes from Rio de Janeiro to ask if the administration of arsenic for moderate periods or the prolonged use of tar externally predispose the recipient in the slightest way to cancer. He states that in the tropics, both east and in the Atlantic, there is in the crews of ships much skin trouble, such as eczema, erythema intertrigo, pruritic conditions, tinea circinata (Dhobie itch), staphylococcal boils, axillary abscesses, and pityriasis. Tinea circinata occurs in epidemic form voyage after voyage in the same ship among the stokers—an exceptionally clean class. Perhaps the two agents most useful and usable under shipboard conditions are tar—either as liquor or picis carbonis—and, to a less extent, according to the late Sir Jonathan Davis in his book, *Skin Diseases in General Practice*, several writers have recorded cases of arsenical hyperkeratosis becoming malignant; workers in tar have long been known to be prone to cancer. He asks whether, this being so, the prolonged use of these remedies in chronic conditions is justifiable. In certain cases of the tinea class, affecting the groins, scrotum, and the parts between the toes, tar lotions are used voyage after voyage on the same person, both for cure and prophylaxis. How far can one go safely with the use of these bodies?

### POISONS IN INSTITUTIONS.

A CORRESPONDENT inquires as to the current regulations which govern the keeping and dispensing of poisons in a private sanatorium. The answer is that the full requirements of the various regulations made under the Dangerous Drugs Acts must be strictly observed. No person in such a place may be in possession of or administer the drugs unless he is a registered medical practitioner or dentist or other person authorized by the Regulations, or unless he is administering the drug under the direct personal supervision of a doctor or dentist, or unless the drug has been supplied on a prescription or dispensed by the doctor for the use of a patient. Doctors and dentists are advised to keep any dangerous drugs when not in use under lock and key as far as possible. This is not actually required by the Regulations, but is obviously a desirable precaution. Copies of the various regulations may be obtained from H.M. Stationery Office, Imperial House, King's-way, London, W.C.2.

### CAN BEACH BATHING BE MADE SAFER?

DR. M. W. BROWDY (London, W.) writes: "Neptune's" letter (September 18th, p. 544) raises a very important problem and is of special interest to me, for an effort to overcome the tragedies he mentions I have invented a bathing costume which I think will to some extent make bathing safer. The various contrivances, such as collars, wings, belts, etc., do not find favour with the public, through being either cumbersome or unsightly. I have suggested a bathing costume which has an extra layer of material encircling the thorax, thus forming a sleeve for a depth of six inches. Within this sleeve there is an inflating chamber made of thin rubber or oiled silk, terminating at one axilla and attenuated at the other, to give freedom of arm movements; over the sternal portion there is attached a small rubber tube with valve for inflation by blowing. One can inflate before or after

entering the water. On deflation the appearance is that of a normal costume. Thus, in an emergency, if inflated, there will be sufficient buoyancy to keep the bather afloat until rescued. "Neptune's" suggestion is rather impracticable and probably dangerous, as a swimmer might become entangled in the ropes.

#### PRURITUS.

DR. ALFRED EDDOWES (London) writes in reply to the request by "W. A." (September 25th, p. 582) for suggestions as to treatment of a case of general pruritus: I advise him to try superfatted boric acid soap, sponging with boric acid lotion, and the application of cold cream (old formula) containing a little boric acid. For severely itching spots try creolin 5ss, mucilage of starch 3iv, water to a pint. The case is probably a *lichen* (a sweet rash) aggravated by hot and changeable weather. Lichen tropicus (prickly heat) has been common during the recent spell of hot weather.

"V. G. E." writes in answer to the same query: Probably one of the causes of pruritus in middle and old age is thyroid deficiency; and this should suggest the administration of iodine in some form, such as colossal iodine, or tinct. iodi mitis mij-v in milk 3j, twice a day.

#### INCOME TAX.

##### *Deduction of Tax from Rent.*

"J. S." explains that in 1922 he paid £4 16s. 9d. property tax (that is, income tax under Schedule A) and the landlord allowed the amount to be deducted from the rent. The authorities have now asked the landlord for payment of £4 16s. 9d. direct, stating that the amount paid and deducted by "J. S." was on a personal assessment under Schedule D.

\* \* The authorities are clearly not entitled to receive more tax from "J. S." and his landlord together than would have been obtained if the question of the tax deductible from the rent had been kept out of the Schedule D assessment—as, in fact, it should have been. "J. S." should ask the authorities to let him have a statement setting out clearly what tax they consider to be due to him (1) under Schedule A as tenant of the property, and (2) under Schedule D as a medical practitioner. If this statement does not enable him to dispose of the matter perhaps he will forward it to us for further comment. On the facts stated the authorities appear to have no legal claim on the landlord direct in respect of the rent assessable under Schedule A.

#### Assessment.

"A. G." holds an appointment under a local authority at a salary of £725, plus emoluments—namely, free house, coal, and light, estimated at £90 for superannuation purposes. He pays superannuation contributions on £815, and has been assessed on that amount for income tax.

\* \* On the facts stated he is assessable in the sum of £725 only; the allowances estimated at £90 are not convertible into money, and therefore, under the well known case of *Tennant v. Smith*, are not chargeable to income tax. It should be added that if "A. G." were in receipt of a salary of £815, of which £90 is estimated to be covered by allowances, the result, as far as tax is concerned, would be different.

#### Motor Car Allowances.

"L. D. T." states that the local inspector of taxes will allow only 15 per cent. depreciation in respect of a motor car, and that he says that if in the future the motor is renewed, no allowance on that account will be made if depreciation allowance has been granted year by year.

\* \* The rate of the allowance is a matter within the jurisdiction of the District (or Special) Commissioners, and "L. D. T." can appeal to them from the inspector's decision. In our opinion, 20 per cent. is not at all excessive for a car undergoing the sort of wear and tear that a practitioner's car usually suffers, and when the car is discarded and a new one purchased for the reason that the old car is no longer suitable, a claim under the head of obsolescence can be made for the replacement cost, less the depreciation allowance given on that car.

"A. M. J." states that he replaced his car in 1924 at a cost of £240, and that amount has been allowed as a professional expense of the year 1924. The result under the three years' average system is that the assessments for 1925-26 and 1926-27 are affected to the extent of £80 each year, but, as he points out, a change to the previous year's basis for 1927-28 will result in his losing the remaining £80, as 1924 will no longer affect the assessment.

\* \* The statutory rules which it is proposed to bring into force for 1927-28 are too complicated to explain here; it may be said, however, that there is no provision for carrying the balance of £80 into the calculation of the assessment for 1927-28. Failing the application of any of the modifications introduced to soften the change from the average basis—and it may be possible to find space at an early date to explain the position more fully in the JOURNAL—"A. M. J." has no remedy.

#### LETTERS, NOTES, ETC.

##### SODIUM TETRAIODOPHENOLPHTHALEIN IN CHOLECYSTOGRAPHY.

MR. W. HARRISON MARTINDALE, Ph.D. (London, W.1), writes: Mr. Cyril A. Raison, in your issue of September 18th (p. 572) was good enough to mention my name in connexion with the above matter. I am now in possession of a large amount of information concerning the compound, both on the chemical side and on the subject of its use as a diagnostic procedure. I do not think it can be too strongly enforced, or too widely known, that its intravenous use, or that of the bromine analogue, may prove dangerous and is hence undesirable. To take a very rough simile, one might employ a strong solution of sodium carbonate, or phenol, with impunity in ninety-nine cases and in the hundredth case the result would be disastrous. While writing on the subject I may mention that there is a slight confusion in vol. ii of the *Extra Pharmacopoeia* in the nomenclature, which should be put right. The impression when writing the book was that the American workers had preference for phenoltetraiodophtalein and the analogous bromine compound. The names, where occurring, should therefore be transposed, together with the formulae, so as to read tetraiodophtalein. The American papers were a little voluminous and difficult to follow. It is of interest that Graham and his co-workers propose now to revert to the phenoltetraiodo compound, which they originally had in view, but personally I do not anticipate that this compound will be any more safe. Administration of the tetraiodophtalein compound by the mouth has, up to the present, proved satisfactory, and I shall be pleased to answer inquiries which medical men may send me.

##### TRANSLUCENT TISSUES.

DR. S. G. MOORE, M.O.H. Huddersfield, writes: No doubt many of my colleagues have seen the wonderful specimens prepared by Professor Spalteholz. For my present purpose the essential thing is that in the specimens the tissues are rendered so translucent that, for example, injected arteries are readily seen in relief in transmitted light. I understand that the process of Professor Spalteholz is a secret. It has occurred to me that if, by any possibility, the process could be applied to living tissues it might restore sight in those cases of blindness due to opacity of the cornea, at least partially. I write in the hope that if the process be not secret some of my colleagues who have the opportunity will make the attempt, and if, on the other hand, it be secret, Professor Spalteholz will either make the attempt himself or disclose such information as may be useful.

##### COITUS INTERRUPTUS.

DR. G. F. GUBBIN (Twickenham, Middlesex) writes: In the past belief in family limitation has been considered to apply only, or for the most part, to the upper and middle classes. But is this true of the present time? For some years I have been attached to a southern London dispensary, with the care of outpatients, and was at first puzzled to account for the number of women of child-bearing age who attended for nervous affections without any discoverable lesion to account for them, and who were in consequence diagnosed as "neurasthenia." Later I discovered that most of these cases, other than those at or near the menopause, had very small families, mostly one or at most two children, the youngest of these 5 to 10 years of age, or even older. The question of "Why no more children had been born?" almost always produced the answer, "Because my husband and I do not wish any more children." The final question, "How do you prevent conception?" resulted in the answer, "By withdrawal." I have now the records of many patients who have given me the answers noted above. The usual bottle of nerve tonic is given, but is accompanied with the advice that "those who act contrary to nature must expect to suffer from upset of the bodily machinery." I am convinced that the limitation of families, as above noted, has become general amongst the better educated members of the working classes, but unfortunately education has not yet taught them that actions contrary to nature are dangerous to health. I have been much interested in the literature which has been published in the last few years on the subject of contraception, but have seldom noticed any allusion to the dangers to the health of mothers as the result of its practice. I hope that the publication of this note may produce the experiences of other practitioners about the prevalence of the above-noted method of contraception and its results.

##### JOHN HILTON.

DR. NOEL R. RAWSON (Whitley Bay) writes: No doubt many correspondents will write to remind Dr. Richard Gilliard (September 25th, p. 582) that in *Members of the Deceased Sir Arthur Keith* devotes the second chapter to an admirable description of John Hilton the man, and of his work as surgeon and pioneer. He will, moreover, find at the head of this chapter a portrait of the robust, energetic Hilton at the age of 65.

##### VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 35, 36, 37, 40, and 41 of the JOURNAL, columns, and advertisements as to particular vacancies, and locumtenencies at pages 38 and 39.

A short summary of vacant posts notified in the advertisement column appears in the *Supplement* at page 160.

THE SCIENCE OF CLINICAL MEDICINE.

OCT. 9, 1926]

An Address  
ON  
THE SCIENCE OF CLINICAL  
MEDICINE.

GIVEN AT THE WESTMINSTER HOSPITAL, OCTOBER 1ST, 1926,  
BY  
SIR ARCHIBALD GARROD, K.C.M.G., D.M.,  
LL.D., F.R.S.,

REGIUS PROFESSOR OF MEDICINE IN THE UNIVERSITY OF OXFORD;  
CONSULTING PHYSICIAN TO ST. BARTHOLOMEW'S HOSPITAL  
AND TO THE HOSPITAL FOR SICK CHILDREN, LONDON.

A VOYAGE down the Thames from its upper reaches to London gives a mental picture of the river, and of its significance, wholly different from that obtained by looking at it from the Tower Bridge. So also it seemed to me, when I was asked to speak to you on this opening day of a new session, that one who has lived through such a period of unrivalled progress in medicine and surgery as the last half-century should have a message to deliver to those who see before them the fruits of that progress, but only as accomplished facts.

It is obvious that the medicine which you are learning to-day is very different from the medicine which we set out to learn fifty years ago. In the interval the work of the bacteriologist and protozoologist has changed our conceptions of the nature of disease, and has revealed exquisite mechanisms by which the organism protects itself against the assaults of the agents of disease. The Listerian methods have revolutionized surgery, and have widened its scope immensely. By combating the insect carriers of those maladies vast tracts have been freed from malaria and yellow fever. From the biochemical side also there have been great advances, and terms such as "hormone" and "vitamin," which embody conceptions of which we in student days had no inkling, have become household words.

New and far more delicate methods of diagnosis have been devised; the range of therapeutic measures has been greatly widened, and even dietetics is being placed upon a scientific footing.

All this has entailed profound changes in the curriculum, and has added much to what you have to learn. Even the longer curriculum is becoming seriously overladen, and the student's burden is causing much concern to his teachers, who look round to see what can be jettisoned. The student himself, I am bound to say, appears much less perturbed thereby.

But not only is the subject which you study, and the curriculum laid down for you, greatly changed; you yourselves have a very different outlook from that of the students of the past. The change of ideals and standards of the student of to-day—the schoolboy of the war time—is not easy to define in words, but is very evident to those engaged in teaching in our schools and universities.

DEMANDS ON THE MEDICAL STUDENT.

I would begin by pointing out to those of you who are just entering upon a medical career that two separate demands are made upon you. The first is that you shall acquire a working knowledge of the sciences upon which medicine—and I use the word in its widest sense—rests. You need to study at the bedside and in the laboratories the signs and symptoms of maladies; to acquire the technique of the therapeutic measures at our disposal, and to become skilled in their application. Without such knowledge and skill no man can expect to impart them in fission to any good purpose; and to impart them is the function of the medical school. The student learns from his teachers at the bedside, from lectures and demonstrations, from practical experience under guidance, and from his fellow students. Lastly, what may be called the atmosphere of his school, that mass of floating knowledge which forms its tradition, and is handed down from generation to generation of teachers and students, plays no small part in his education.

But, apart from his professional competence, the medical man, who is brought into peculiarly intimate contact with his fellow men, must have other qualifications for his task.

He needs to be equipped with tact, resourcefulness, courage, and prudence. He must have patience with fads, consideration for his patients and their friends, sympathy with suffering, and gentleness of touch and voice. Much indeed is asked of him, but without these qualities, he is never so able, he will make but a poor practitioner. Of this side of the medical profession I do not propose to speak further, seeing that its scientific side is my theme to-day; but I am anxious to emphasize, at the outset, the importance of the human aspects, which each student must learn for himself, aided by the example of his elders.

FIFTY YEARS AGO AND NOW.

The student of fifty years ago almost always entered upon his studies with the intention of taking up some branch of practice, or of entering one of the public services. Few alternatives were open to him. There were no bacteriologists, pathology was synonymous with morbid anatomy, and the men who, from the end of the eighteenth century onward, had laid the foundations of biochemistry in this country were all practising physicians. They, and others of scientific bent, pursued their researches in the period of waiting for practice and in its intervals, but nevertheless they were pioneers, not only of the medical, but of other sciences also.

Nowadays the position is very different. In addition to the physiologists, most of whom still go through the medical curriculum, not a few qualified men turn aside from the path of practice and devote their lives to teaching and research in the various branches of pathology or in pharmacology.

This has its advantages and its disadvantages. On the one hand, some men of scientific tastes and interests—for whom the work of the laboratory has great attractions, whereas the practice of medicine has none—enter the profession, and by their researches contribute greatly to the advances of our science and art. In that way medicine is the gainer. But, on the other hand, there is real danger that the great majority of men of scientific bent will turn aside and desert clinical work, in order to devote themselves to work in the laboratory. This tendency is increased by the attitude of some of the laboratory workers, who regard clinical medicine as a subject hardly worthy to attract men of scientific ability. So there has been a drift apart of the ward and the laboratory, which is far more pronounced in this country than elsewhere, since it is only recently that complete clinical units, with wards and laboratories under a single head, with trained assistants, have been established amongst us.

THE SCIENTIFIC SPIRIT AND CLINICAL MEDICINE.

It will be my endeavour to convince you that there is abundance of work to be done on clinical subjects by strictly scientific methods; and seeing that much of the information to be sought can only be got by clinical research, it would be nothing short of a disaster if all, or nearly all, those qualified by tastes, training, and opportunities to pursue clinical investigations on such lines should desert the wards for the laboratories.

The study of pure pathology and of the problems of immunity entails experimental investigations by men highly trained in the subjects and the methods employed, in bacteriological technique, and chemical manipulation; and those who devote their lives to such work are most valuable members of the profession. But, on the other hand, the mere fact that a piece of work is done in a laboratory does not make it a scientific research; and the routine of clinical pathology is not more scientific than the examination of a chest, the diagnosis of a lesion of the brain, nor even than the careful taking of notes at the bedside.

It is not to be expected that everyone who enters upon the practice of medicine will approach his work in a strictly scientific spirit, and with zeal to contribute to the advancement of knowledge, although he must employ scientific methods. It must needs be that the bulk of the members of our calling will, owing to the incessant demands upon them, have little time or opportunity for investigation on broad lines. They must be content, willingly, to carry out the day's work with practical skill and

common sense, making good use of what they have learnt from their teachers and from their own experience. Yet not a few of those so circumstanced make important contributions to medical knowledge.

On the other hand, it must not be forgotten that the knowledge upon which the art of medicine is based has been gained by work done on scientific lines, by methods of observation and experiment. All the great therapeutic advances of recent times have been the outcome of scientific investigation; and in medicine, as in other sciences, investigations carried out with no practical aim have proved very fruitful in practical results. It is to scientific research that we owe aseptic surgery and all that it has rendered possible, the conquest of insect-borne diseases, the banishment of the typhoid terror from campaigns, the discovery of the vitamins, and the utilization of hormones. No better example can be quoted than the history of insulin, from the experiments upon dogs of von Mehring and Minkowski to its widespread benefits in the present day.

Now that the curriculum is becoming so crowded there is being put forward a view that in the medical training unnecessary stress is being laid upon the earlier stages, and that the student learns much more than he needs of the details of anatomy, and even of physiology. Believe me, this is a dangerous doctrine. Anyone engaged in clinical teaching knows that the clinical clerk or dresser who has been well trained in those subjects has a quite different grasp of medicine or surgery from that of a student who has only acquired the minimal amount of knowledge needful. However good a practitioner he may make, the man whose knowledge of physiology is slight is little likely to advance the science of medicine; for pathology is anatomy and physiology gone wrong.

I know well that there is a limit to what a student can do in the time allowed, but in building a house it is a bad plan to skimp the foundations. Given solid foundations the upper stories may be added at discretion. The great majority of us learn what anatomy and physiology we acquire during our student days, but medicine and surgery we are teaching ourselves each day of our active lives.

#### BRANCHES OF CLINICAL SCIENCE.

The science of clinical medicine has several distinct branches, in which different means are employed and different results are aimed at, and these it will be desirable to consider in turn.

In the first place, the clinician seeks to know the nature and seat of the patient's illness, and without such a diagnosis his treatment must needs be perfunctory. His next aim is to do what he can for the relief of the patient's symptoms, and, if possible, for the arrest of his malady. These are the direct and immediate aims of the practitioner, but behind and beyond them is the study of disease, as it manifests itself in the living human subject, the gaining of new knowledge, the advancement of our science and enlargement of our art.

#### THE SCIENCE OF DIAGNOSIS.

The science of diagnosis is, in the main, a science of observation, the aim of which is to detect in the living patient processes and lesions which are beyond our reach, but which would, in most instances, be revealed at a *post-mortem* examination. Yet it rests largely upon *post-mortem* teachings, and all who aim at becoming capable diagnosticians should take advantage of every opportunity afforded to them of seeing, and whenever possible conducting, such examinations. Such opportunities are most common during student days, and only too many of us regret in after life the neglect of such opportunities; for morbid anatomy, one of the most important subjects in the medical curriculum, can only be learnt by personal observation. Do not forget that there is an immense difference between facts which we *know* and facts with which we are merely acquainted. Facts which we know are not those about which we have read, or have heard in lectures, but those which we have observed, apprehended, and confirmed for ourselves. We need no *memoria technica* to recall a fact which we *know*.

Some diagnostic methods are simple and involve merely

the use of our senses—of our eyes, ears, nose, and fingers; others require the use of instruments of more or less complexity; and others, again, involve chemical or bacteriological examination of the blood or excreta, by methods usually carried out in the laboratory. It is hard to realize how recent most of our diagnostic methods are. Auscultation and percussion were only brought into use at the end of the eighteenth century; the clinical thermometer came into general use in our hospitals as recently as the seventies of last century. Blood counts began in the same decade, and the importance of leucocyte counts was only recognized in the nineties. Since then our diagnostic resources have been largely increased. The discovery of the tubercle bacillus, and its ready detection in the sputum of many sufferers from pulmonary tuberculosis, opened the way for wide applications of clinical bacteriology—the detection of various bacteria on the one hand, and the agglutination tests on the other. More elaborate means, such as the Roentgen rays and the electrocardiograph, have rendered our findings far more precise, and we now have methods of testing the functional efficiency of such organs as the liver, kidney, and pancreas.

As long ago as the middle of the last century uric acid was detected, and estimated, in the blood of the gouty, but in recent years methods have been devised which render possible the estimation, not only of uric acid, but also of glucose and urea, in a few cubic centimetres of blood.

All these refinements and advances have not superseded the older and simpler methods. It is as necessary as it ever was that the medical man shall be trained to make use of all his senses, supplemented by the stethoscope and thermometer. A laboratory is not always within reach, and it is often necessary to act before a bacteriological report can be had. Moreover, the older methods have been improved, and pulmonary tuberculosis is now usually diagnosed by auscultation and percussion at a stage at which it would have escaped recognition fifty years ago.

Auscultation and percussion are strictly scientific methods. Consider for a moment how by such means it is possible in very many instances to ascertain beyond a doubt that a patient's lung is consolidated, or that the pleural cavity contains fluid; that his heart is hypertrophied or dilated, or that there is narrowing of valvular orifice or leaking of a valve. Such diagnoses involve accurate observation and sound interpretation of the signs observed, and the confidence with which we make them is due to confirmation of such diagnoses many *post-mortem* examinations.

Lesions of the nervous system often present difficult problems of localization, for the brain and spinal cord are wholly out of reach of direct examination. Yet by making use of the findings of experimental physiology, and by teachings of morbid anatomy, it is usually possible to make a correct diagnosis of the seat and nature of a cerebral spinal lesion—just as a man who is thoroughly conversant with the telephone system may, by comparison of observations made in several branch offices, diagnose accurately the place, and form a shrewd notion of the cause, of an interruption in a central office which he cannot visit.

A diagnosis often involves replies to two questions, namely, Where is the lesion? and What is its nature?—the answers often hang together. For example, the signs and symptoms, in a particular case, point to a lesion of the head of the pancreas, and experience teaches that such a lesion is almost certainly a carcinoma. Yet a diagnosis may be right in one respect and wrong in the other.

There are some people who possess a natural diagnostic insight, and others who acquire such an insight by long experience. The accumulated impressions, derived from cases seen at various times, may point to a right solution. Just as a child spells out the letters of words, and the beginner translates laboriously what he reads in a foreign tongue, so the medical student runs over in his mind possible causes of an observed sign or symptom. But experience allows such conscious effort to be dispensed with; the foreign words come to convey their meaning direct, the clinical picture suggests a correct diagnosis.

One of the dangers which beset the medical student to-day is that he may be tempted to neglect that thorough grounding in auscultation and percussion and the simi-

## THE SCIENCE OF CLINICAL MEDICINE.

chemical and microscopic tests which can be made at the bedside, and may come to rely upon reports from the laboratory of examinations which he has not himself carried out. To this danger all examiners in medicine and surgery are keenly alive.

### SCIENTIFIC THERAPY.

The treatment of disease, also, is developing along scientific lines, and in no part of the field of medicine has more conspicuous progress been made during the last fifty years. The advances of surgery, which have been rendered possible by Lister's researches, are obvious and generally recognized. It is the privilege of the surgeon to obtain more definite results; he removes the inflamed appendix and the danger to the patient is at an end; by the sacrifice of a limb the whole body may be saved. The physician, on the other hand, has usually to help the patient to hold his own whilst Nature works a cure. It is one of the most important lessons learned during the last half-century that the physician is not the protagonist in the fight with disease, and the patient's body the battlefield, but that Nature has provided the patient with power to produce drugs far more potent than any which we were wont to use, and so discriminating that they can destroy the particular attacking bacteria or neutralize the toxic substances which they produce. The extensive use of sera and vaccines in the present day represents our attempts to utilize Nature's own remedies; and we may hope that, in due course, we shall be able to give them as pure products, free from undesirable admixtures.

Many of the old drugs, introduced at the dictates of fantastic theories, of astrology or of magic, are falling into disuse, and others, of proved value, are being investigated on pharmacological lines, and their mode of action and the limits of their utility are being determined. But we are bound to admit that amongst the old drugs, introduced on no scientific grounds, there are not a few which are of great value, and have for centuries contributed greatly to the healing of the peoples. Now that we know better how and when to use them their utility is greater still.

Dietetics, for long the most backward and empirical branch of medical treatment, is coming within the scope of scientific therapeutics. The discovery of the vitamins, and the appreciation of the importance of caloric value of foods, are signs of the times, but we still give advice on diet for which we can give no scientific reasons and the utility of which rests upon no firm basis of experience.

The advance of science is furnishing us with new methods of treatment, with most of which we are still feeling our way. I need only to mention Roentgen rays, radium and its emanations, light and ultra-violet rays, the recent developments of electrical treatment, of massage and manipulative measures. Lastly, a tribute must be paid to the nursing methods of the present day, which strengthen our hands so greatly in the fight against disease.

### THE PURSUIT OF CLINICAL RESEARCH.

So far I have spoken of scientific knowledge and method, as applied to the recognition, control, and treatment of disease, but what I particularly wish to emphasize is the fact that the clinical observer has abundant opportunities for the study of disease as seen in the human subject—in other words, for the pursuit of clinical research. Much of the knowledge so obtained is not to be had from experiments on animals; for a human patient can describe his sensations with greater or less accuracy, and can tell us of the medical history of himself and his family. Such work as that on the sensory nerves which we associate with the name of that great observer Henry Head could not be done in any other way.

Although it is established that, in the majority of instances, illness results from the invasion of the body by micro-organisms, vegetable or animal, or by poisons of inorganic origin, and although such immense help has been got from the culture and study of such organisms and of their effects upon lower animals, and by the experimental study of the phenomena of immunity, we cannot learn in the laboratory all that we need to know about disease.

What we call disease is the response of the organism to

the invasion of the agents of disease, and, seeing that no two individuals are exactly alike either in structure or in chemistry, sickness does not conform to any single model; each individual case calls for careful observation. Owing, as I believe, to their chemical individuality different human beings differ widely in their liability to individual maladies, and to some extent in the signs and symptoms which they exhibit. Hence it will be found a useful maxim that there is no such word as "never" in medicine. Rules which appear to be immutable turn out to have their exceptions.

Many idiosyncrasies are obvious and notorious, such as the sensitivity of individuals to special drugs, or particular articles of diet, which have no ill effects upon others. As examples may be quoted the manifestations of sensitivity to fever, and in varieties of asthma. Light also is an agent which affects various individuals in very different ways. Usually beneficent, it produces unpleasant effects upon the skin of some individuals, and to a very few who are victims of congenital porphyria it is a veritable poison.

Again, the minor injuries which are necessary accidents of the wear and tear of life vary greatly in their effects. In the bleeder a trifling knock may produce grave trouble in a joint; in victims of that strange anomaly fragilitas ossium it may cause a fracture; in a gouty subject it may induce an attack. So do our idiosyncrasies and our circumstances contribute to the moulding of our maladies. All this is the true basis of the doctrine of diatheses now unduly neglected.

### PIONEERS IN CLINICAL RESEARCH.

It is by clinical observation, controlled by morbid anatomy, that almost all the maladies with which we are familiar have been differentiated. By the study of groups of allied cases, of the signs and symptoms met with during life, and of the lesions found after death in fatal cases, the door has sometimes been opened to wide extensions of physiological and pathological knowledge.

One of Nature's experiments, the placing of a lesion in some particular spot, may serve to reveal the functions of the part affected. Let me illustrate this point by a particular instance.

In the year 1855 Thomas Addison, one of the greatest clinical observers which this country has produced, published a description of *The Constitutional and Local Effects of Disease of the Suprarenal Capsules*. In the preface to his pamphlet—one of the classics of medical literature—after pointing out that the pathologist may sometimes be able to throw much light upon the functions of diseased organs, and that we are apt to forget how much of our physiological knowledge has been revealed by casual observations of the effects of disease, he goes on to speak of the adrenals, and adds: "It is as a first and feeble step towards inquiry into the functions and influence of these organs, suggested by pathology, that I now put forth the following pages." Yet that "feeble step" was destined to be epoch-making; for Addison's description of the disease which goes by his name was the starting-point of our present knowledge of the functions of the endocrine glands; and the recognition of the hormone action of their secretions, and of their mutual interdependence, constitutes one of the most conspicuous advances of physiology and pathology during the last half-century.

It is true that the malady which we call exophthalmic goitre was described by Caleb Parry, Graves, and Basedow at a much earlier date. Those observers recognized the association of the cardiac and ocular symptoms with enlargement of the thyroid gland, but it was not until much later that it was realized that the affection of that gland was the pivot of the clinical picture, and that to derange-ment of its functions the other phenomena were due.

Since Addison's day clinical observation has continued to play a conspicuous part in this field of pathology, as witness Gull's work on myxoedema, the recognition of acromegaly by Marie, of Brown-Séquard, the recognition of anæmia by Frohlich, and the surgical labours of Harvey Cushing and others.

Let us pause, then, to consider how Addison set to work. He noticed that a certain group of symptoms was apt to occur in association—namely, anæmia, debility, remarkable feebleness of the heart

action, irritability of the stomach, and a peculiar dingy or smoky discoloration of the skin—and that in every case in which this syndrome was met with extensive disease of the adrenals was found *post mortem*. So constant was this association that, in the later cases of the series, the disease of the adrenals was predicted during the lifetime of the sufferer. Addison's disease is decidedly uncommon, but, as it is uniformly fatal, he was in a position to verify his conclusions in the majority of the cases.

For my next example I will go to the remarkable series of papers by William Jenner on the differentiation of typhoid and typhus fevers, in which also we may admire the workings of a great clinical talent. Jenner's conclusions were based upon a series of sixty-six fatal cases of continued fever, all of which had come under his own observations in the London Fever Hospital, and in all of which autopsies had been made. The first of these papers was published in 1849, and at that time, although various observers, in this country and abroad, had maintained that typhoid and typhus fevers were specifically distinct, the trend of current opinion was towards their inclusion as varieties of the same disease. To quote his own words, Jenner

"considered that it was necessary to begin *de novo*, and consult only the voice of Nature—convinced that although the most intellectual might fail at first to comprehend her often ambiguous language, yet her most humble votaries might, by patience and daily watching, by keeping honest record of every sound she uttered—by joining letter to letter, adding word to word and line to line—at last spell out her meaning, and so reach that rank which the great master of induction tells us man may legitimately hope to attain—namely, that of her interpreter."

This is the true scientific spirit, and following its guidance Jenner was able to settle the point at issue once and for all, on evidence which carried conviction.

He investigated the place of origin, age, and circumstances of each patient in his series, collated the observations relating to each symptom in turn, and showed that the outcome of clinical observation accorded with that of *post-mortem* examinations, and that from the character of the rash alone it was possible to predict the presence or absence of intestinal lesions.

Jenner's monograph is one of the foundation stones of the statistical method in medicine, which he defended warmly against those who prefer to rely upon general impressions. "Who," he asks, "can tell what general statements are worth, without knowing on what evidence they rest? One man's many is another man's few; one man's frequent is another man's seldom."

In the histology of neurology examples abound of the employment of clinical methods in scientific research. Of one who may justly be styled a clinical genius, Hughlings Jackson, it has been said with truth that "his advent infused a new spirit into neurology, and was the beginning of that systematic orderliness which now characterizes neurology, more perhaps than any other branch of medical science." Both physiology and pathology owe to him a great debt; and I believe that I am right in saying that his contributions to science, from the discovery of the association of convulsive attacks with lesions of the cerebral cortex, to the wide and important generalizations upon which his fame largely rests, were the outcome of bedside observation controlled by morbid anatomy.

The brilliant researches of James Mackenzie, begun, and largely carried out, in the intervals of a busy general practice in a northern town, lend further support to my thesis; for that work has opened a new era of cardiac investigation, and has changed the aspect of the physiology and pathology of the heart.

I have chosen a very few examples from the past—some of them from days when the clinical thermometer was still unknown, and the bacterial origin of disease was not dreamt of—of researches which conform to every canon of science, and which were carried out at the bedside and in the *post-mortem* room by British clinicians who have obtained places in the medical Valhalla. It would be easy to enlarge the list so as to embrace such men as James Paget, Jonathan Hutchinson, W. B. Cheadle, and that great physician whose death we have so recently deplored, John Thomson of Edinburgh. The inclusion of workers in other countries would greatly swell the roll, and I might equally well have taken my examples from men now living. But,

for my purpose, and for the support of my thesis, the examples quoted will suffice.

If, with the far scantier means at their disposal, the clinicians of the past were able to accomplish so much, how much more may be expected from those of the present and future, who are so far better equipped? Although it is true that the nuggets lying upon the surface have been picked up, mining operations, for which this generation is well equipped, should reveal much that is still hid.

In my young days the maps of Africa showed a border of the known around vast areas of the unknown; and in the medicine of to-day there are still large blank spaces to be filled. What do we really know of the true nature of the leukaemias, despite the many differential blood counts of recent years? These carry us to a point, and seem to be unable to take us further. A new road needs to be blazed out, by the collaboration of the laboratory and the ward.

#### SCOPE FOR SCIENTIFIC WORK IN CLINICAL MEDICINE.

If, as I have tried to convince you, there is abundant scope for scientific work in clinical medicine, why is it necessary to point this out, and why do we so often hear the contrary opinion maintained, especially by laboratory workers? Is it not because medical men too often do not realize the requirements of scientific method? If we are to hold our own as members of the army of research, we need to see that our work is up to the required standard; that our observations are sufficiently precise, and are confirmed by the method of control; that our statistics will bear examination by statisticians, people whom it is not easy to satisfy, and that our hypotheses are legitimate inductions from facts which are clearly established.

There are, however, obvious difficulties which make it hard and often impossible for the clinician to be as exact in his methods as he would wish. Medicine is always in a hurry. The patient and his friends are only too apt to mistake scientific caution for incompetence; to demand a cut-and-dried diagnosis in an impossibly short time; and to estimate a ready dogmatism above a reasoned uncertainty. Time is often pressing, and the doctor is obliged to act upon very incomplete evidence, lest, whilst he waits for certainty, valuable hours must be lost. He cannot always put his treatment to the test by trying one measure at a time; and, again, he is bound to forego any diagnostic test, or even a thorough examination, if it appears to him that it might in any way be harmful to the patient. These are only a few of the hindering factors which are familiar to all practitioners.

You will have to realize that to a large section of the public all science is under suspicion, and scientific medicine is distrusted. A profession which makes a free gift to mankind of all its discoveries is widely regarded as a close corporation of people who look askance at men cleverer than themselves, merely because they have not had a medical education, or because they base their treatment upon heterodox theories. This phase of thought is by no means helpful to him who would advance the knowledge of disease, and, through knowledge, its treatment.

In conclusion, let me repeat that for the clinician, as for the laboratory worker, and especially for both working in co-operation, there is abundant scope for original investigation—that highest product of the scientific spirit. We are not all built to do such work, and there are excellent investigators for whom an obvious practical aim is a necessary stimulus to research; but for those who are content to seek knowledge for its own sake there are great rewards; for the discovery of a new fact, however small a one, or the framing of a conception which throws a beam of light into some dark corner, brings a satisfaction which is without alloy.

Yet the way of the investigator is rough, and there are many disappointments to be faced. In the words of Ecclesiasticus:

"For at the first Wisdom will walk with him by crooked ways and bring fear and dread upon him, and torment him with her discipline, until she may trust his soul and try him by her laws. Then will she return the straight way unto him, and comfort him, and show him her secrets."

May she show her secrets to those of you who shall elect to tread her path.

## An Address

ON

## PROFESSIONAL CAREERS.

DELIVERED AT

KING'S COLLEGE HOSPITAL, OCTOBER 1st, 1926,

BY

SIR HUMPHRY ROLLESTON, BART., K.C.B., M.D.,  
REGIUS PROFESSOR OF PHYSIC IN THE UNIVERSITY OF CAMBRIDGE.

Your presence here to-day proves that you have entered on a profession with a choice of fields of activity probably unequalled in any other, and presenting great contrasts in the circumstances and positions of its members. To take up the wrong branch, to be a misfit, may be a tragedy, and it is therefore essential to consider carefully this momentous decision. Some of you may have already settled on your future, and there may be compelling reasons for this; but otherwise it is wiser to wait and to do the day's work, which is exacting enough; to attempt now any decision as to the particular line you will eventually follow may be premature—namely, before you have seen enough to be able to know what really appeals most forcibly to you, what you are best suited for, and how far this is possible. The data may not be available until after qualification, when unexpected opportunities may arise, or circumstances show what is your true bent. There is much wisdom in the advice "Do not specialize too early," for the important point is to get a good general grounding in the vast subject which you propose to profess. In the meanwhile there are some general considerations on the careers open to you.

In some respects the medical profession, especially at the present time, compares favourably with other professions. In the first place, with the expansion and rapid development of medicine there are more opportunities and varied openings than ever before. Secondly, apart from accidents, illness, and grave misconduct, a competence or living wage is within the reach of practically all qualified medical men who choose to work. The panel system has, in spite of the initial forebodings and opposition, really improved conditions for the rank and file of the profession. As a profession medicine does not bring wealth or a great position to more than a few, but it has an immense amount of gratuitous work to its credit, and is exposed to the frequent danger of infection from attendance on the sick, and the occasional risk of vexatious legal actions for supposed malpraxis and improper certification of the insane. To enter on "the physic line" as a means of livelihood is justified by the results, but as a path to great material prosperity the way is long, treacherous, and may land the traveller in a slough of disappointment. In spite of Sir Robert Peel's dictum that "Nothing is so misleading as facts except figures," it may be a comfort to remember that statistics got out at various dates by Sir James Paget,\* Sir Squire Sprigge (1906), and Mr. E. M. Corner (1920) show that on an average over 75 per cent. of medical students obtain a qualification, and that according to the first two authorities 66 per cent. of those qualified have reason to be satisfied with their professional success.

It may be interesting to contrast the financial rewards of the medical and legal professions. As medicine is an almost universally essential profession, practically all qualified men can earn a living; inquiry from men of acknowledged experience shows that before the war the average professional income was about £500 a year, and that now it is about £750, in both instances gross, so that with the present high income tax it is not much more than formerly. On the other hand, the number of barristers briefless, whether voluntarily or of necessity, is comparatively large, whereas the prizes are much greater and more numerous among barristers than among medical men. This might seem to be contrary to the usual relation between supply and demand. But according to Adam Smith the

wages of labour in different employments vary according to the probability or improbability of success in them, and he instances the almost uniform success attained by apprentices to shoemakers, with the twenty to one chance of earning a living in the law, and adds that "in a perfectly fair lottery those who draw the prizes ought to gain all that is lost by those who draw blanks, and that in a profession in which twenty fail for one who succeeds, that one ought to gain all that should have been gained by the unsuccessful twenty." Now in accordance with this axiom it would appear that as the vast majority of medical men succeed in earning a living the winners of great prizes should be exceptional, and so it works out.

So far reference has been made only to the popular, material, or even sordid standards of success, and it should be unnecessary to proclaim the higher motives that may make the pursuit of medicine a satisfying career—the intellectual interest in the attempt to solve the innumerable problems presented by the sick; the opportunities for studying the nobilities and frailties of human nature; and last, the personal and almost sacred call of the service of our fellows. After all there is much truth, if a little exaggeration, in the forcible dictum that "Medicine is a noble profession, but a damned bad trade."

## GENERAL PRACTICE.

General practice is still, in spite of increasing specialism, the future field of activity for the largest number—probably three-quarters—of qualified medical men, and there is plenty of scope and opportunity. Any medical man or woman can be on the panel for the fifteen million insured persons in England and Wales, and the financial and other conditions on the panel are superior to those of its predecessors the clubs and friendly societies. In England there are at present 12,696 men on the panel, or nearly half (46 per cent.) the estimated 27,600 men practising in England; but there are only 434 women on the panel, or one-fifth (19 per cent.) of the 2,209 women in practice. For these figures I am indebted to Dr. Smith Whitaker of the Ministry of Health. This rather striking difference in the sex personnel of panel practice may be in part due to women preferring to confine their work to their own sex and to children. But this is not the whole story, for unfortunately at present the public as a whole have not become accustomed to women doctors, and as a rule the panels of women doctors are not crowded. Time no doubt will cure this, as other inequalities, but in the meanwhile women doctors are not finding it so easy to earn a livelihood in general practice as their brothers. The profession received a large influx of women during, and of both men and women after, the war, and the peak of the wave in qualifications has only recently been reached, so that there is some reason to fear a temporary overcrowding in the profession. A number of official posts in public health, infant welfare, and so forth in this country, in India, in the Zenana Mission, and elsewhere in the mission field, are available, in which women doctors can find congenial occupation and a living.

It is sometimes thought that the public medical services encroach on the general practitioners' preserves, and in time will lead to their exclusion. But Sir George Newman, who is in the best possible position to know, points out that in reality the reverse is true:

"For the Poor Law medical service has 4,000 medical officers for outdoor medical relief, practically all of whom are private practitioners; the Post Office list of 3,500 medical men are all practitioners; out of 1,459 medical officers of health, 1,100 are private practitioners, and only 359 are whole-time officers; of the 1,630 medical men engaged by local education authorities in the inspection and treatment of school children, 1,000 are in private practice; of 1,770 certifying factory surgeons, all, hardly with exception, are private practitioners; and the whole of the national insurance service is in the hands of private practitioners."

Some other lines of work allied to general practice may be briefly mentioned. Examining for life insurance is usually a small item in a general practitioner's life, but some men by holding appointments under several offices spend most or even all of their time in this work. It is, of course, true that the chief medical officerships of large insurance companies are usually held by consultants and hospital physicians.

\*At one of his introductory lectures Abernethy looked round at the crowd of students and exclaimed as if in painful doubt, "God help you all! What will become of you?" His successor, Sir James Paget (1829), attempted to answer this question by analysing what became of a thousand of his pupils within fifteen years of their entrance to St. Bartholomew's Hospital.

With the progress of medicine to a preventive standpoint the logical importance of establishing periodic overhauls of the adult population may be expected to be more widely recognized and acted on, as in this way the causes of early disorders may be removed and so the sequence of serious results prevented. If and when periodic overhauls, twice or three times a year, become recognized in much the same light as a visit to the dentist is now, a fresh line of work allied to insurance practice will be opened up. Police surgeons and appointments to big business firms, to look after their staff, again are nearly always part-time occupations; but in the future it is probable that industrial medicine will bulk more largely than it does at present, and provide more berths for medical men who will devote their whole time to this branch of work, which provides much opportunity for interesting investigation. A good example of this is the recent recognition of squamous-celled carcinoma, usually of the scrotum, among the "mule spinners" or cotton operatives, who during their work lubricate with a mineral oil the spindles of the spinning mules. The Home Office's Departmental Committee Report (1926) records 539 cases (450 of the scrotum).

Temperament or circumstance will no doubt largely determine the choice of general practice in preference to entrance into the fighting or other service or taking up consulting or some special line of practice. Many men are individualistic, and prefer to be their own masters rather than to be under official control. A love of country life, and the human interest in getting to know their patients from the cradle to the grave, may make a man decide to devote his life to a labour bringing with it more love and respect than wealth or professional reputation. Heredity in the form of a father's practice awaiting him may make it a natural means of following the line of least resistance to tread in the paternal footsteps. I know medical families of seven generations in England and in Scotland; Georges Clemenceau, ex-Premier of France, was the seventh medical member in lineal descent of a family which practised the healing art for three hundred years without a break; and America can boast of the Porter family of eight generations of doctors from 1654 (Browning). There are other reasons, and among them desire to be married is not an unknown factor, for starting in general practice. The mention of marriage, in which haste is not essential to ensure happiness, recalls the business marriage or partnership, which also has its pitfalls as well as its advantages. It should not be entered into without due consideration and careful inquiry, and, as Mr. W. E. Hempson (out of the fullness of his experience of many partnership disputes referred to him) has said, a preliminary courtship, such as an assistantship with this further relationship in view, is eminently desirable.

With the changes time has brought about, men in general practice, who become the guide, philosopher, and ultimately familiar friend of their patients whom they bring into and see out of the world, have also changed, for their medical education and general equipment have greatly improved. They have thus become less dependent on the help of specialists and consultants, with whom to some extent they therefore compete. It has been thought by some that eventually general practitioners will become squeezed out by specialists and consultants on the one hand, and on the other hand by preventive and social medicine—such as school, tuberculosis, and venereal clinics, and maternity and child welfare centres. But the general practitioner is the essential element in the medical service, and his elimination would be a most serious loss. Just as they have altered in the past, so should they accommodate themselves to changing conditions, to a larger measure of team work, to a greater share in preventive medicine, and to a responsible part in public health organization.

A general practitioner has to possess a knowledge of every branch of medicine, in fact to be in miniature an all-round specialist, with the proviso that he also knows his limitations—what he can safely do and what he should leave to others; for in these days, with the great and ever-increasing complexity of medicine a real all-round specialist is of course impossible. This difficulty has to some extent been met by team work; firms of general practitioners so

constitute themselves as to cover the ground of the various branches of medicine, surgery, and gynaecology more or less completely, each partner devoting himself to some particular line of work. Thus, in choosing a new partner, consideration is given to applicants with such qualifications as a special surgical or even radiological bent, and the existing partners may from time to time take post-graduate courses so as to become recognized locally as experts in diseases of the throat or eye, urology, and so forth. It is thus possible for a general practitioner to develop into an expert specialist and eventually to set up in a big centre; indeed, his all-round knowledge of the whole art of medicine is a very valuable asset to him as a specialist.

#### LAY MEDICINE AND MEDICAL CULTS.

In the sphere of everyday medicine, especially in that conducted by general practitioners, the competition of amateur doctors and numerous cults or stunts has always played and, unless human nature alters in an unexampled manner, always will take a prominent part, which must be accepted in a philosophic spirit. A fundamental principle of preventive medicine is education of the public in personal hygiene, and this may lead to the acquisition of that small amount of knowledge which is proverbially dangerous, and may encourage treatment not only of self but of dependants and friends. As many persons, acting on the assumption that forty years of life make an individual either a physician or a fool, are convinced that they are as good as, or better than, doctors, a considerable amount of rather irresponsible treatment—in other words, a more advanced grade of domestic medicine—is likely to result. It must be remembered that such lay medicine is largely the outcome of past medical opinion or advice, and so up to a certain point is often sound. From such domestic medical practice it is but a step to an addiction to patent proprietary potions and pills, with which, as proved by their widespread advertisements, so many people dose themselves and others so freely and sometimes not too wisely. But just as the lay public are not justified in believing that a patent medicine taken under their own direction is necessarily an infallible panacea for what they think they are suffering from, so it would be unwise for the medical profession to jump to the opposite conclusion that they are all useless or worse. Proprietary medicines are sometimes derived from physicians' prescriptions for combinations of drugs proved by experience to be specially effective; some, indeed, such as chlorodyne and James's fever powder, have been copied in the *British Pharmacopoeia*. When the composition of a patent medicine is known—and it will be advantageous when a note of their composition on the label is legally enforced—there is ground to show whether or not it should be prescribed.

The cults of medicine, such as homoeopathy, Christian science, osteopathy, and chiropractic, are fashions, and the successors of others that have had their day and ceased to be remembered, such as Perkins's "metallic tractors," which had a great vogue at the beginning of the last century for drawing out disease from the body. But orthodox medicine also has its fashions, such as indiscriminate bleeding, salivation, and setons; it is always wise to find out if there is any germ of good in every new thing, however much it may be boomed and advertised. What in one generation is regarded as the obsession of a crank, such as the open-air treatment of tuberculosis by Dr. G. Bodington of Sutton Coldfield, Warwickshire, in 1840, may subsequently become recognized as a valuable form of treatment; in the past useful hints have been obtained from bone-setters, and manipulative surgery, which is part of orthopaedics, may embody some of the methods of osteopaths. The success which sometimes follows much-vaunted cures, especially when attended by great pomp and circumstance, such as touching for the king's evil, the séances of Count A. Cagliostro (1745-1795), and those of F. A. Mesmer (1733-1815) with his magnetic cabinet, which seems to have been reincarnated in Albert Abrams's box, and many modern fashions, is chiefly due to the impression made on the imagination or to "suggestion"; as Oliver Wendell Holmes said, "So long as the body is affected through the mind no audacious device, even of the most manifestly dishonest character, can fail of producing

occasional good to those who yield it an implicit or even partial faith." But every successful doctor, by kindly and firm encouragement, is consciously or unconsciously practising suggestion.

It has been thought that education of the masses, and of the classes, is the only way of getting rid of quackery; but with all the modern improvements and spread of education there is as much, or more, irregular practice as in the past. That great ability and learning do not prevent such infatuation is shown by many examples in the past as in the present—for example, Sir Kenelm Digby and the "sympathetic powder" (1658), and George Berkeley, Bishop of Cloyne, universally acknowledged to have been one of the most accomplished of men, who, in *Philosophical Reflections and Inquiries concerning the Virtues of Tar Water* (1744), advocated tar water as a panacea. The encroachments of irregular practitioners on orthodox medicine are annoying, but, as already said, they will last in some form or another as long as human nature is what it is.

#### CAREERS IN THE SERVICES.

In the past men sometimes entered our profession because, being debarred by bodily defect or failure in negotiating examinations from the executive branches of the army or navy, their ambitions were to some extent met by being medical officers in the services. The call of adventure and the itch to travel attracted some entrants into the fighting and colonial services; a life of varied interests, an assured rate of pay, and the prospect of a pension to provide for retirement also weighed in the choice of the services; but the shortage in the services at the present time, possibly an aftermath and revulsion from the war, shows that these factors are somewhat in abeyance, and accordingly short commissions of four years or so with a gratuity on leaving, which helps in starting a practice, have been established. The opportunities for research and investigation have much increased in the naval and military medical services, and that devotion to scientific work is compatible with gaining the highest offices in the medical department of the army was shown by the appointment of the late Lieutenant-General Sir William Leishman as Medical Director-General. The new problems in connexion with aviation attract keen men of the kind wanted in the Royal Air Force. Tropical research, with its great potentialities, is specially open to those in the colonial service.

The increasingly active health services provide a large number of official positions, not only part-time, which, as already mentioned, are chiefly occupied by general practitioners, but whole-time appointments, and these posts are likely to increase in number and importance. Appointments in fever and mental hospitals and sanatoriums are, of course, whole-time, and provide opportunities for research and openings for men who are attracted to these special branches of medicine.

#### CAREERS AS SPECIALISTS.

The development and ever-expanding scope of the healing art have long made it impossible for one man to be encyclopaedic, much less to attain the technical skill to be competent in all its branches, and specialism has, after the necessary period of probation and some disapproval, become fully justified and recognized. But it is of comparatively recent growth; Sir Benjamin Brodie (1783-1862), President of the Royal Society and of the Royal College of Surgeons, is made responsible for the dictum "A specialist is half a quack." Special hospitals, such as the Royal Ophthalmic (1804), Royal Hospital for Diseases of the Chest (1814), and the Royal Ear Hospital (1816), have been in existence for more than a century, but forty years ago or less specialism was not more than tolerated by the leaders of the profession. It is important that medical men should not specialize too early, before they have obtained a broad view of medicine as a whole, otherwise they will not be able to see the wood for their intense focusing on the constituent trees. It is unwise to build a complex structure of unseasoned material, for it may subsequently shrink into a useless if not harmful article. Wise specialism is of the greatest advantage for the progress of medicine, but its followers should know something about everything medical as well as everything about their own branch.

Without taking a reactionary view, there is a danger that specialism may be exaggerated and that parts of medicine which should be within the reach of every competent medical man may be prematurely elevated into a specialty; in ancient Egypt there was a phase (B.C. 500) when each disease had its practitioner, who confined his activities to that one condition. To be a clinical specialist has mercenary advantages, for practice comes earlier and the lucrative rewards may be considerable.

The pathologist, bacteriologist, serologist, and biochemist belong to a special branch of medical practice which has a progressively increasing scope of activity, as is shown by the overwhelming flood of new work on these fundamental sciences; from a material aspect, the recommendations of the Royal Commission on Health Insurance, if carried into effect, will increase the number of official posts available for those whose abilities and temperament render them better suited for laboratory investigations than for clinical practice, and who therefore prefer the quiet pursuit of truth in the laboratory to that of wealth in a limousine or a Ford. Intellectually, laboratory research—with the possibility of making a permanent addition to knowledge, which will advance scientific medicine and so benefit suffering humanity—has an appeal of the highest order, and all honour to those who are able and willing, for we are not all so gifted, to follow the call. It can hardly be too often emphasized that, in the best interests of all concerned, the clinician and the laboratory worker should be in constant and close touch, and indeed in the whole-time directors of professional units they are combined. The laboratory worker should, for his own sake, have a full and experienced training in clinical medicine.

Radiology is one of the newest specialties, and from the amount of technique necessary is fully justified in being so regarded. The interpretation of the appearances seen on the screen and in films demands an extensive acquaintance with anatomy and physiology, and above all with clinical medicine. The action of x rays and of the rays of radium provides great opportunities for research, both biological and physical; the influence of radiation on the tissue cells, in destroying and in stimulating them, and on the blood, and the therapeutic effects on malignant disease, have raised problems which await further investigation and are therefore attractive to men keen on research.

Anaesthetics is a branch of therapeutics, and has become a specialty in large centres where there is sufficient demand for men who devote their whole time to this work. On the other hand, it is hardly marked off so sharply as are the other specialties, and is often adopted as a part-time occupation by men in general practice or while waiting for some post on the surgical side of the hospital. The subject is allied in practice more with surgery than with medicine, and offers considerable opportunities for research into the various new methods that have recently been employed.

#### CAREERS IN CONSULTING PRACTICE.

Consulting physicians and surgeons, though often dubbed "specialists" by the public, are not usually regarded by their professional brethren in the same category as those who practise ophthalmology, gynaecology, laryngology, otology, psychiatry, orthopaedics, and other legitimate specialties. The general consulting physician and surgeon have had their wings somewhat clipped by the growth of specialism, and indeed hospital physicians now commonly pay more particular attention to some branch of their subject, such as diseases of the heart, lungs, nervous system, or alimentary canal. It is more especially the general consulting physician who has suffered, and the wait for monetary success may be so long that without private means the struggle is disheartening. Few consulting physicians were more successful than Sir Andrew Clark (1826-1895), who said that he had to work ten years for bread, ten years for bread-and-butter, and twenty years for cakes and ale; it is not given to all to practise for forty years, or if they do, to reach the material rewards of the last stage. Money may be a mark of success, but there are other conceptions of success, and it has been written "What shall it profit a man if he gain the whole world and lose his own soul?"

With surgeons the outlook is very different, for their

technical skill in operating has been enabled, by the discoveries of anaesthesia and antiseptic and aseptic methods, to become most successful in combating disease in all parts of the body, especially cancer and acute inflammation in the abdominal organs. But in populous centres surgeons are largely concentrating their activities in some special direction, such as the abdomen, malignant disease of the breast, or surgery of the brain. Of the two great, if artificial, divisions of the healing art, pure medicine and surgery, the second is naturally the more attractive, for the benefits wrought by operation are much more obvious and spectacular than those in a physician's practice. The operating surgeon has invaded, and with good justification, realms of disease formerly regarded as sacrosanct to the physician, and the rewards are much greater; thus gynaecology in its advance has become surgical, and much of the treatment of digestive disorders is on operative lines. A budding surgeon should now be a Fellow of the Royal College of Surgeons.

Time was when the physician was paramount, but now there are not wanting definitions of a surgeon which point to his supremacy, such as "A surgeon is a physician who can use his hands"; "A surgeon is a physician and something more"; and perhaps the arresting, if somewhat intriguing, auto-definition of the distinguished President of the Royal College of Surgeons, "A physician doomed to the practice of surgery." The financial rewards are much greater and begin earlier than in the physician's earthly course; but, on the other hand, a surgeon's flood of activity ebbs sooner, and the wear and tear of a surgeon's exacting life are much greater than in the case of his medical brother. Writing last year about this subject, as illustrated by the staff of the Manchester Royal Infirmary in 1900, Mr. A. H. Burgess pointed out that the death rate on the surgical side was nearly five times higher than among the physicians. This may be an exceptional instance, but the risks run by a surgeon from infection and overstrain cannot be doubted by anyone who follows Mr. Burgess's example of analysing now the composition of hospital staffs as existing a quarter of a century ago. Forty or fifty years ago the best men flocked to the medical side of a teaching hospital, and I remember a waiting list of twenty possible candidates for the post of assistant physician at St. Bartholomew's Hospital. It is very different now.

But before a decision is made on the question to be or not to be a surgeon, it may not be unwise to consider the possibility of another swing of the pendulum. Since the war general practitioners, as a result of their experience abroad, have done much more of their own surgery than before; and, as already mentioned, team work or group organization in which one partner in a firm of practitioners devotes himself to surgery has come in, and is likely to increase. The future of the general surgeon is a matter for careful consideration by those who are thinking of reaping a harvest twenty years hence. The various specialties—laryngology and otology, and proctology (which tend to spread from the orifices further into the alimentary canal), orthopaedics, genito-urinary and venereal diseases—have narrowed the former vista of the general surgeon. Further, if, as is within the bounds of imagination, discoveries, such as that of Gye and Barnard, lead to the prevention and cure of cancer, and the immunology of the future to the prevention of inflammation of the vermiform appendix, gall bladder, and other forms of inflammatory abdominal disease, the activities of the operating surgeon would be greatly curtailed, and little more than accidents and deformities would remain.

The distinction between physicians and surgeons is artificial in principle, for it depends on the possession of the technique to carry out one kind of the proper (surgical) treatment completely. It would be in the patient's and the medical man's interest and to their advantage if the diagnosis and treatment—whatever it might be, drug or operation—were carried out by the same person. Thus a neurologist should be equally capable both to diagnose and to remove a cerebral tumour, as indeed some now classed as surgeons are; there would thus be analogous thoracic and abdominal experts, following, indeed, the practice of the already fully recognized specialties, such as ophthalmologists, laryngologists and otologists, and gynaecologists.

There is a last piece of advice that I would venture to give to the young consultant in the early stage when he has to "learn to labour and to wait," and, being anxious about his future, is naturally afraid of missing any step on the ladder. It is to utilize a year or so at the beginning of the waiting period, when the mind is elastic and fertile in ideas, to do some work of permanent value. So often a man seizes the opportunity of gaining an assistant physicianship or assistant surgeonship at a hospital without a medical school and becomes a slave to seeing out-patients in an unprofitable race against the clock, when by spending the same time in experimental research he would establish a claim to a better appointment, even though he may appear to be somewhat later in the start of the race with his peers.

## British Medical Association.

### PROCEEDINGS OF SECTIONS AT THE ANNUAL MEETING, NOTTINGHAM, 1926.

#### SECTION OF SURGERY.

Sir D'ARCY POWER, K.B.E., M.B., F.R.C.S., President.

#### DISCUSSION ON CEREBRAL TUMOURS.

##### OPENING PAPERS.

I.—PERCY SARGENT, C.M.G., D.S.O., F.R.C.S.,  
Surgeon to St. Thomas's Hospital.

TWENTY years ago Victor Horsley addressed the seventy-fourth Annual Meeting of the British Medical Association upon the technique of operations on the central nervous system. This address is remarkable chiefly for the fact that much of it, if read to-day, would, except perhaps to those who happen to be brought frequently into contact with cases of cerebral tumour, appear fresh and novel; not because the surgery of the brain has stood still, but because Horsley was so far ahead of his time in this field.

Horsley constantly insisted that surgery must not be regarded, as even to-day it is in some measure regarded, as a *dernier ressort*. He condemned what was known as "expectant treatment" in terms so characteristic that I cannot refrain from making a brief quotation from an address which he delivered in Berlin in 1910.

"A few years ago," he said, "all, and even now most, cases of intracranial tumour died without really receiving any treatment at all, for, since no drug is known to have any influence on neoplastic tissues, the classical administration of potassium iodide is merely a ritual. . . . By a singular cynicism, the origin of which I cannot trace further, the unfortunate sufferer from intracranial tumour is commonly said to receive 'expectant treatment.' Considering that in the absence of any active surgical treatment the only thing to be expected is death, the term 'expectant treatment' has always to my mind carried with it its own condemnation for inhumanity."

In opening this discussion may I express a hope that it may not be wholly or even chiefly devoted to the mere technique of craniotomy, but that it may bear upon the question of our responsibility towards patients with intracranial tumour, and how far our attitude may have been modified by the experiences and advances of the past twenty years. Starting from the fact that a cerebral tumour will, if left alone, ultimately prove fatal, and that no drug and no method of actinotherapy has as yet been found to have any curative effect, it follows that at the present time the patient can look to surgery alone for a possibility of cure, or even of relief from his sufferings. There are, of course, cases of intracranial disease, the symptoms of which may closely resemble those of cerebral tumour, but the diagnostic methods of to-day are such that errors but rarely arise. Further, it is in most cases possible to predict, not only the exact situation, but also the probable nature of the tumour. In this respect some, but not too much, importance is to be attached to the length of history as distinguishing benign from malignant tumours. A history extending over several years naturally suggests that the tumour is an innocent one, but it is surprising

how long a history is occasionally elicited in cases of glioma. On the other hand, a benign tumour may for years cause no symptoms which attract attention, and then rapidly make its presence manifest by causing some vascular or other change in its neighbourhood.

The situation of the tumour affords some help towards predicting its nature. Thus, tumours of the cerebral hemispheres are rarely any but gliomata or endotheliomata. In the frontal and post-central regions gliomata are twice as common as endotheliomata, in the occipital lobe six times as common, and in the temporal lobe thirteen times as common. Cerebellar tumours, on the other hand, are almost invariably gliomata; cerebello-pontine tumours are mostly neuro-fibromata; and pituitary tumours are most commonly adenomata.

Lesions other than true neoplasms which cause symptoms indistinguishable from those of tumour, such as localized syphilitic and tuberculous masses, chronic abscesses, and hydatid cysts, are all rare, and when they do occur there is usually some point in the history, or in the state of the cerebro-spinal fluid, to afford a clue as to their nature.

Let me now briefly consider the four groups of intracranial tumour which are most commonly met with.

### 1. The Gliomata.

Unfortunately the great majority of cerebral tumours are of a malignant character—malignant, that is to say, by reason of their progressive and infiltrating growth. They never produce metastatic deposits, nor do they ever spread beyond the limits of the brain itself. In my own experience, leaving aside cerebello-pontine and pituitary neoplasms, the gliomata constitute nearly 80 per cent. of the total number of intracranial tumours.

It has long been recognized that these growths vary greatly in their degree of malignancy, and that they can be grouped according to their gross structure and clinical course. There are, for example, those which undergo complete cystic degeneration, leaving little if any recognizable tumour tissue, and with no infiltration of the surrounding brain. Others are firm, solid, circumscribed, though not encapsulated tumours, sometimes capable of complete removal. These are cases eminently suitable for radical surgical treatment, and are to be clearly distinguished from the more common rapidly growing and infiltrating kinds for which palliative measures alone are available.

Recently Bailey, working in Cushing's clinic, has made a most valuable contribution to our knowledge of these tumours from the histological aspect, recognizing some fifteen different varieties with histological features corresponding in a suggestive manner with their clinical behaviour. It is, however, only by exploratory operation that the various kinds can be differentiated, so that anyone who refrains from giving his patient such chance as surgery affords may deprive him of his sole hope of relief. I cannot give here detailed statistics, but will summarize as briefly as possible the results of some 300 operations for glioma, so as to give a general idea of what my own experience leads me to expect from surgical intervention. In most cases the operation was that of simple decompression, but in many instances it included also partial or seemingly complete removal of solid tumours, or emptying of gliomatous cysts. In about twenty cases radium also was employed—50 to 100 mg. for twenty-four hours. About 25 per cent. of patients with cerebral gliomata die shortly after operation, and about 50 per cent. die within eight months. About 25 per cent., however, make good recoveries, and some have been able for several years to lead useful lives and to earn their living.

With cerebellar gliomata the results are somewhat better. The operative mortality is less than half that of the cerebral gliomata—28 per cent. are alive and well at an average period of three years after the operation, whilst the average survival period of the remainder is thirteen months. To show how well worth while it may be to give these unfortunate patients the chance of benefit which operation offers, I would like very briefly to mention three cases.

1. A man, aged 47. Partial removal of a cerebellar glioma five years ago, recrudescence of symptoms four months later; removal of a further mass of growth, and insertion for twenty-four hours of 60 mg. of radium. To-day he is well and able to work, with no bulge and very little sign of cerebellar disturbance.

2. A man, aged 27. Evacuation of cerebellar gliomatous cyst sixteen years ago. To-day he is well, at work, and married.

3. A man, aged 19, with severe cerebellar symptoms. Evacuation of a gliomatous cyst containing 2 ounces of fluid. Six years later he writes: "I feel fit in every way. The swelling at the back of my head has completely gone. My occupation keeps me out of doors most of the day in all weathers. I often go for ten or fifteen-mile tramps, and have recently returned from a cycling tour of 250 miles, so I think I must be pretty fair."

### 2. The Endotheliomata.

These are benign, encapsulated tumours of remarkably slow growth, arising from the cells of the arachnoidal tufts which are concerned with the absorption of cerebro-spinal fluid. They never invade the brain, but occupy cup-like depressions from which they can easily be enucleated. Complete removal, however, entails the excision of the overlying dura mater to which the tumour is attached, and this cannot always be done with safety on account of the proximity of the great venous sinuses in the immediate neighbourhood of which these tumours are most commonly found. They are, unfortunately, far less common than gliomata; in my own experience of some 400 operations for tumour of the cerebral hemispheres the proportion was as two to seven. Of this number only 75 per cent. could be completely removed, and of these nearly 50 per cent. made good recoveries and are alive and well at the present time. The patients who recovered fall into two classes: first, those who are restored to their normal lives and occupations without any neurological defect (22 per cent.); secondly, those who remain to a greater or lesser extent neurologically imperfect owing to various degrees of palsy or fits (38 per cent.). Of those patients in this series who are still alive and well, two were operated upon seventeen years ago, three eleven years ago, and the rest between four and seven years ago. The operative mortality is high, and compares unfavourably, in my own experience, with that of the gliomata. This is partly due to the fact that the operation is necessarily more severe, and partly because I have included all my earliest cases, when the operative technique was comparatively crude and ill developed, when localization was less accurate, and when enucleations were often mistakenly carried out in the presence of a greatly raised intracranial pressure.

### 3. Cerebello-pontine or Extra-cerebellar Tumours.

Of these tumours 90 per cent. are neuro-fibromata. They are usually firm, solid, encapsulated tumours, but are sometimes quite soft and may even be completely cystic. Arising from the eighth nerve just within the internal auditory meatus, they enlarge that orifice, sometimes to a remarkable degree, and on complete specimens of such tumours there can usually be seen a nipple-like projection which has occupied the meatus. For a long while, perhaps for many years, deafness and noises in the head may have been the only symptoms complained of, and sometimes the deafness is only discovered accidentally when it is already complete. By Bárány's tests the functional state of the vestibular nerve can be ascertained with precision, and these tests are positive at an early stage in the course of growth of an auditory nerve tumour. Very often the corneal reflex of the same side is diminished or absent, and this is so frequently the case that the corneal reflex, as well as the vestibular functions, should be tested in all cases of nerve deafness, as the coexistence of these signs would, even in the absence of all other symptoms, be sufficient to suggest the presence of one of these tumours. As the growth enlarges other cranial nerves become involved, and symptoms of disturbance of cerebellar function appear. Sooner or later the tumour compressing the pons and medulla blocks the aqueduct of Sylvius, and ventricular distension results. Then appear the classical symptoms of cerebral tumour—the headache, vomiting, and papilloedema. When this stage of general increase of intracranial pressure is reached operation becomes at once more difficult and more dangerous, and the outlook more grave.

It would naturally be expected that these tumours—benign, encapsulated, capable of early and accurate diagnosis, and easily accessible to the surgeon—would constitute the most favourable form of intracranial tumour for complete removal. This, however, is not, in practice, the case, for their position in relation to the medulla and its blood

vessels renders their removal exceedingly hazardous. A series of lamentable disasters (only one survival out of nine) led me to abandon the operation of enucleation and to adopt the method of removing as much as possible of the tumour tissue from within the capsule by fragmentation and suction. The operative mortality has fallen to 14 per cent., and the results in the remainder have for the most part been very satisfactory.

#### 4. Pituitary Tumours.

These cases have to be divided into two groups. (1) Pituitary tumours proper, mostly adenomata, arising in the sella turcica and invading the cranial cavity. Of these there have been thirty-four cases with nine deaths, the majority of the fatalities having naturally occurred amongst the earlier operations. This series includes four transphenoidal operations with one death, and thirty transfrontal operations with eight deaths. I was at one time fortunate enough to have a run of fifteen cases without a fatality. (2) Suprapituitary tumours, arising above or in close relation with the sella, including infundibular, interpeduncular, and frontal lobe tumours and cysts of various kinds. Amongst these there have been six temporal operations with one death and twenty-nine transfrontal operations with three deaths.

While it is a comparatively simple matter to indicate statistically the results of this or any other operation as regards immediate mortality, it is not easy to set out in any such precise manner the far more important results which concern the condition of those who emerge successfully from such operations. Judged first from the point of view of visual disturbance—the outstanding symptom for which, at present, pituitary operations are generally performed—the gain has in practice proved to be such as greatly to outweigh the operative risks, and it is quite certain that when these cases are submitted to operation at an earlier period, before the power of recovery of the visual paths has been seriously impaired, the results as regards vision will be still more gratifying. It is for the ophthalmic surgeon, more than anyone else, to make himself acquainted with the progress and possibilities of pituitary surgery, for it is chiefly to him that these patients entrust themselves for advice and treatment. Judged from the point of view of comfort, the relief of pressure afforded by these operations results in freedom from headache and often an improved mentality. The patients become brighter, more alert, and better able to carry on their occupations. It is too early to say anything as to the effects from a standpoint of endocrine function. There have in a few instances been rapid and definite alterations in the metabolic and other disturbances, but how far these may be but transitory is not at present known. They are, however, such as to suggest that, with the increasing safety of the operation, it may come within the scope of legitimate surgery to operate for the arrest of acromegaly in its early stages.

The further improvement in outlook for the sufferers from cerebral tumour which is so greatly to be desired lies partly, of course, in perfection of surgical technique, but even more in earlier diagnosis and more accurate localization. The onset of the classical symptoms of cerebral tumour—headache, vomiting, and papilloedema—should be regarded as marking the commencement of the terminal stage, and it is of vital importance that surgical intervention should take place before the general intracranial pressure has become conspicuously raised for there is no single factor which so dominates the situation, and upon which success or failure so definitely depends. Although it is true that symptoms may develop rapidly in some cases owing to changes such as haemorrhage and oedema in and around a tumour, the growth of the tumour itself, even with most cases of glioma, is remarkably slow. This is amply proved by a minute inquiry into the history of a large number of cases. Any disturbance of cerebral function, whether in the direction of overaction or defect, especially when of a persistent and progressive character, should stimulate a most searching investigation into the history and lead to the minutest and most thorough neurological examination. It is surprising to find in how many cases the history shows that some slight disorder of cerebral function has been present for many months or years, and

this is true even with some of the gliomata. The largest tumour which I have yet removed, an endothelioma weighing 6½ ounces, came from the brain of a man who had been known to have hemianopia for two years, whose discs were normal, and who had never had a headache.

Horsley went so far, sixteen years ago, as to lay down two propositions: first, that "every case of focalized epilepsy not definitely proved to be idiopathic in origin must be treated by exploratory operation"; and secondly, that "every case of progressive motor or sensory paralysis of intracranial origin must be treated by exploratory operation." Since that time so much has been learnt regarding localization of function, the significance of slight departures from the normal, especially as regards sensation and the special senses, and also as regards the meaning of changes in the pressure and constitution of the cerebro-spinal fluid, that operations upon the brain are becoming less frequently exploratory, and are more often planned with the definite object of carrying out the appropriate attack upon a tumour the situation and nature of which have been confidently diagnosed beforehand. But in the main the propositions which Horsley laid down stand, and should at least occasion serious thought.

#### II.—H. S. SOUTTAR, C.B.E., M.Ch., F.R.C.S., Surgeon to the London Hospital.

**A NEW FORM OF CRANIOTOME FOR OPENING THE SKULL.**  
IN the surgical treatment of cerebral tumours the first problem presented to the surgeon is that of opening the skull, and it cannot be denied that the methods at present available for this purpose leave much to be desired. In general terms three methods are in common use. In the first a series of trephine holes are made through the skull along the intended line of section, and these are joined by means of some variety of cutting forceps; in the second the Gigli saw is substituted for the forceps; for the third method a powerful electric motor is necessary, and the procedure consists in drilling a series of holes and joining these either by means of a circular saw or some form of bur electrically driven. The first two methods are certainly primitive, and they demand a degree of exertion on the part of the surgeon which is detrimental to his manual skill when he comes to deal with the brain itself. The third method is effective, but it involves very serious trauma to the patient, and the cumbersome appliances involved limit its use to large institutions where these can be provided and kept in working order.

I am venturing to place before you a method of an entirely different nature, by means of which the skull can be divided by the exclusive use of hand tools with great facility, and with so little violence as to be easily accomplished in the conscious patient under local anaesthesia. The method is specially designed for the formation of large osteoplastic flaps, and it enables the surgeon to form these with a facility, a rapidity, and a precision unattainable by any other method.

The instrument consists essentially of a stud and a lever. By means of a locking device the stud is securely fixed in a trephine hole previously cut at the centre of the proposed bone flap. Around this can turn a long lever on which slides an adjustable carriage carrying a cutting chisel, which closely resembles the parting tool used in turning. This tool can be advanced from a socket, which supports it, by means of a screw, so that the depth of the cut can be adjusted with the nicest accuracy. The method of procedure is as follows:

A very large flap consisting of scalp only is turned down. It must be so large as to overlap by fully half an inch the furthest limits of the bone flap which is to be formed. As there is no anastomosis whatever between the vessels of the scalp and of the bone, the turning down of the scalp does not interfere in the slightest with the vitality of the bone, whilst it greatly facilitates access to the latter. At the centre of the projected bone flap the muscle and pericranium are divided and drawn aside, and a trephine hole is cut with a special brace. Into this trephine hole is inserted a split stud resembling an expanding mandrel.

and into the centre of this is screwed a pin which forces it open and locks it into place. The lever is now dropped over the pin and held in place by a nut, the carriage is adjusted to the correct radius, and the cutting tool is advanced until it just projects from its housing. It will now be found that on swinging the lever round its fixed fulcrum the skull can be cut with astonishing facility and without the slightest suspicion of violence. The cuts are taken in long sweeps, omitting the base of the flap, which is always so arranged that the skull at this point is thin. After each cut the tool is advanced a fraction of a millimetre, and another cut is taken. In a remarkably short space of time it will be found that the thinner parts of the skull have been penetrated, and the cutting is now limited to the thicker part, where hard bone can still be felt at the bottom of the slot. The form of the tool precludes any possibility of injuring the dura, but as soon as the seeker shows that the dura has been reached, these parts of the incision will naturally be left alone. The bone is by this means completely divided over three-quarters of a circle, and two flat steel levers are now inserted into the slot which has been formed. Very slight pressure on these levers is required to crack the thin base of the bony flap, which is now turned down still attached to the soft parts, usually formed by the temporal muscle. The tool is set at such an angle that the margin of the bone flap is bevelled, and therefore when the latter is replaced it lies snugly in position against the corresponding bevel of the skull itself. I know of no other method by means of which such accurate and firm coaptation can be obtained.

There is no instrumental limit to the size of the bone flap which may be formed, and a bony disc six inches in diameter can quite easily be turned down in the temporal region. For most operative work, however, a flap of from three to four inches in diameter will be sufficient. One of the most remarkable features of the instrument is the rapidity with which these large flaps may be formed; the average time taken for cutting the bone has in my own experience varied from two to two and a half minutes. The tendency of modern cerebral surgery is to explore the brain through very large openings, usually situated either in the temporal or the occipital region. It is for the first of these that the instrument has been devised, and although it may be applied to other regions, it is in the temporal region that its peculiar value appears.

There is one point in the use of the appliance to which I ought to refer—namely, the cutting of the trephine hole. This has to be done with great accuracy, and I employ for the purpose a special form of trephine which differs in many respects from that in common use. In the first place it is mounted in a large brace so that it can be operated rapidly and without fatigue. In the second place, the centre on which it turns screws down; it is never removed, but is gradually withdrawn by means of a screw as the trephine advances through the bone. As the trephine is cylindrical the possibility of plunging has to be guarded against, and it is therefore surrounded by a collar running on a screw thread on its outer surface. The collar is always so adjusted as not quite to touch the bone. Quite apart from its use in connexion with the craniotome, this form of trephine with the receding centre presents very great advantages over the old-fashioned instrument, for, turning as it does upon a firmly planted centre, it can be so applied as to cut obliquely through the outer table of the skull and to arrive absolutely flush at the inner surface, even where the inner and outer surfaces are not parallel.

### III.—A. P. BERTWISTLE, M.B., CH.B. LEEDS, F.R.C.S. Ed.

#### LOCALIZATION BY X RAYS.

THE purposes of this paper are to give a brief outline of the researches on which our knowledge of the functions of the cerebral cortex is founded, and to describe a method which renders it possible to determine the position of a cranial defect and to trephine more nearly over the centre of a tumour when its position has been determined by the symptoms present.

#### PREVIOUS RESEARCHES.

Our knowledge of cortical functions rests on the following:

##### 1. Anatomical Considerations.

Gennari's discovery on February 2nd, 1776, of the "lineola albidior admodum eleganter"—the line which still bears his name—marked the dawn of research on these lines. Work has been done on cells and tracts.

*Cells.*—For the lower functions of the cortex, such as sensation and motion, this method stands without rival. Campbell has shown that the histology of the precentral gyrus was in accordance with pathological finding, and that the visuo-sensory area and post-central gyrus were sharply demarcated. He made equally important observations on the intermediate precentral and superior temporal gyri.

*Tracts.*—These may be studied by serial sections of the white matter or by the myelination method of Flechsig, who grouped the fibres into primordial, intermediate, and terminal, the last being characteristically human. Campbell found this method very useful for the visuo-sensory area, but even its originator found it subject to modifications and reservations.

##### 2. Post-mortem Evidence.

At times this has yielded valuable results. The symptoms have been recorded and the position of the lesion in the cortex discovered at autopsy. Material falls under the following headings:

(a) *Trauma.*—Whilst eminently suitable for study during life traumatic cases are of doubtful value after death, as the injury is so severe that the white matter, or even the basal ganglia, may have suffered.

(b) *Cerebral Haemorrhage.*—This includes softening, which usually results from the haemorrhage. Here again the injury is too extensive for accurate investigation. Campbell investigated 200 of these cases, and came to the conclusion that destruction of the cortex without injury to the underlying fibres must be of extreme rarity, so that safe judgement can seldom be given.

(c) *Post-amputation Changes.*—The microscopic examination of the brains of patients who have undergone removal of a limb is in a different category. Campbell writes:

"As a result, either of section of the fibres with which they are connected, or of suppression of the energy they elaborate, the cortical motor cells controlling muscles in the amputated limb undergo a change described by Marinesco as 'réaction à distance,' and from a careful examination of the distribution of these changes, important results are forthcoming."

The cells become globose and faintly staining before disappearing. This alteration is best seen about two years after the operation, since changes are then limited to the cells presiding over the amputated muscles. Later, atrophy is seen in the cells presiding over muscles immediately proximal to the amputation. The change is akin to Wallerian degeneration, but occurs much later, as would be expected from the greater number of neurons to be traversed. Among this group must be placed an instructive case reported by Shaw Bolton, in which he examined the calcarine region in a man who had had optic atrophy for many years.

(d) *Tumours.*—Autopsies on cases of cortical tumours are of very doubtful value. Cortical tumours cause death by interfering with the intracranial tension and circulation of the cerebro-spinal fluid, which only occurs at the terminal stage. The interference with intracranial tension may have been in itself responsible for the symptoms, especially if the higher functions were involved. The same can be said of abscess, the effect of which is too diffuse for accurate work. Cysts and granulomata, when single, are comparatively rare, but are of considerable value, especially when small.

(e) *Meningitis.*—On rare occasions meningitis has yielded information.

(f) *Localized degeneration* by amyotrophic lateral sclerosis, when presenting symptoms during life, has at death been found to show, histologically, localized degeneration of areas of the brain. Campbell writes:

"Natural lesions such as cerebral softening, tumour, and trauma, which form the basis of most of the clinical observations, are only in rare instances limited in their effects to allow of safe judgement."

### 3. Animal Experiments.

The experimental researches of Sherrington and Grünbaum and Horsley are classical, as are those of the pioneers in this method—Hitzig and Fritsch (1870). The devices employed were ablation and faradic stimulation, Sherrington using the more accurate unipolar method. It is largely on these experiments that our knowledge of the human cortex has been founded. While invaluable in the study of such coarse functions as motion and sensation, they are quite unsuited to the investigation of the higher developments, such as thought and speech, which have no counterpart in animals. Even in the case of the motor area Horsley shows that its extent diminishes the higher we ascend in the animal scale. The analogy between the human brain and that of animals, even the ape's, has been pushed too far.

### 4. Operation Findings.

The case is one either of fracture, possibly depressed, or of tumour. Certain symptoms being manifest, a trephine opening is made and the area of brain exposed is identified. The extreme difficulty of identifying any gyri through a small opening of perhaps four square inches is at once obvious.

### 5. Electrical Stimulation.

This has been tried by faradic current in the conscious individual by Horsley and Cushing. Alfred Gordon, who used unipolar stimulation in two cases, writes:

"The facts prove, I believe conclusively, that the results of faradization of the cortex cannot be considered as an absolutely reliable means for an exact and precise delimitation of the motor centre; the motor region is more extensive than faradization seems to prove."

Head expresses dissatisfaction thus:

"Results of electrical stimulation of the cortex, more especially the motor area, no longer appeal to the more thoughtful investigators."

### 6. Post-operation Findings.

These must of necessity furnish us with our best results; the cases can be examined under the best possible conditions and at regular intervals; yet it is here that we find least work has been done. In certain selected cases Head adopted the following method:

"The head of a male body was selected which corresponded as nearly as possible in its measurement with that of the patient whose wound we intended to localize. The exact extent of the loss of bone was marked out on the scalp and holes were drilled through the skull to mark its dimensions. Through these a coloured fluid was passed with a small brush, to fix the relation of the bony opening to the surface of the brain. Then the skull cap was removed and a cast taken of its inner surface. This gave us a solid reproduction of the brain covered by its membranes, on which were indicated the limits of the external wound. The situation and course of the principal fissures was determined by careful dissection and drawn in the cast. Thus we finally obtained a record of the area occupied by the wound on the surface of the brain in relation to the main landmarks of cerebral topography."

The chief objections to this method are its tediousness and costliness, one cadaver being required for every two patients investigated. The second is the difficulty of fixing the interaural and nasion-inion lines—which are over the hairiest part of the scalp—for the purpose of taking measurements from them.

### AUTHOR'S METHOD.

The method to be described involves the use of a key radiogram, and a simple inexpensive instrument called a gyrometer.

#### Base-line.

The line chosen is almost horizontal, running from the glabella to the external occipital protuberance and passing just above the point where the pinna joins the scalp. While its origin and termination are not ideal, it possesses the unique advantage of being available for both clinical and radiological purposes. The line is much more readily fixed than a sagittal one, which would be quite unsuitable here, as it would be calibrated from the periphery, where the inches are least dependable. It is of importance that three-quarters of it in males is hairless, and they furnish the majority of depressed fractures. With the exception of the occipital pole, the rays are centred on the most important functional parts of the cortex. Should any shrinkage occur in the cadaver's brain it is minimal at the centre of this line. A small advantage is that ear-cones may be dispensed with, the line of rivets serving to determine whether the radiograph is a pure lateral one or not.

#### Preparation of the Key Radiogram.

A scale was prepared consisting of a strip of watch-spring, 7 in. (17.5 cm.) long, the ends of which were connected together by a piece of elastic. At intervals of an inch, seven strips of spring, 4 in. (10 cm.) long, were fastened at right angles to it, the central one being marked 00 inch. Holes an inch apart were made in the verticals, through which were threaded silver wires.

The head of a dissecting-room subject (aged 39) having been radiographed to make certain that there was no great brain shrinkage, the cerebrum was removed in the usual way and its membrane, stripped off. A photograph was taken to indicate

1, Anterior limb, Sylvian fissure. 2, Ascending limb. 3, Posterior limb. 4, Inferior precentral fissure. 5, Rolandic fissure. 6, Superior precentral fissure. 7, Interparietal fissure. 8, Superior temporal fissure.

the type of brain being dealt with; fortunately, it proved to be particularly well hardened; the cerebral hemispheres weighed 41 oz. (1½ kilos). A mixture of red lead and warm vaseline was now painted on the more important sulci and a second photograph obtained. The brain—covered with tissue paper to prevent dissemination of the opaque material—was replaced, the skull cap and scalp adjusted into position, and the scale fitted on the unshaven head. It passed from the glabella to the external occipital protuberance, lying just above the junction of the pinna and scalp. The circumference of the head in this line, which is known as the base-line, was 22½ in. (56.2 cm.). The scale having been adjusted until its central point 00 lay midway between the glabella and external occipital protuberance, the upright-wires were placed at right angles to it and fixed by means of thread wound round the head. The breadth across the head along each vertical from base-line to base-line was measured. Only the central five gave a precise reading.

A pure lateral radiograph was now taken; that this lateral position was obtained is shown by the base-line being straight—any deviation causing a curve to appear convex upwards or downwards, as the case may be. The following precautions were taken: the tube was 2½ ft.

(0.75 metre) from the head, and the rays were centred on the point 00.

The curvature of the head renders only the central area available for accurate localization; it represents an area of about 16 sq. in. (100 sq. cm.). This limitation precludes study on the occipital region. The key is of the greatest value for the supramarginal, angular, superior temporal, and pre- and post-Rolandic convolutions, all of which have been insufficiently charted in man.

#### The Gyrometer.

To localize the brain underlying a cranial gap the following measurements are necessary:

1. The point at which a vertical dropped from the centre of the gap cuts the base-line.
2. The vertical height of this line.
3. Dimensions of gap.
4. Circumference of the head on a line drawn through the glabella and external occipital protuberance. This will be referred to as the G.O. or base-line.
5. Breadth of head in the line of the above vertical.

For routine work 1, 2, and 3 are all that are required, the distances being transferred directly to a dolichocephalic or brachycephalic key, whichever type of skull the patient possesses. Messrs. Arnold have made a simple, inexpensive instrument for measuring these distances and for preserving a radiographic record; it may be called a gyrometer, in that it indirectly measures gyri. The instrument is composed of a thin strip of celluloid half an inch wide with inch graduations and 0.2 inch subdivisions (0.5 cm.). The central point was marked zero. The

ends of the strip are united by a piece of elastic, which serves to keep the celluloid in close apposition to the head. The celluloid and elastic form the base-line on the patient's head. The celluloid strip is provided with a cursor of similar material marked from 0 to 4 in. (10 cm.), which slides along it at right angles. A piece of elastic connects the free end of the cursor with the elastic part of the base-line in such a way that it can move with the former. The elastics are provided with tapes whose inches continue those of the celluloid strips; by this means the circumference of the head in the G.O. line, and its breadth at any point, can be easily read off. For radiographic purposes the strips are studded with lead rivets at intervals of an inch, the central one being square to distinguish it from the others.

After combing the hair suitably and possibly wetting it, the gyrometer is applied to the patient's head in such a way that the main strip passes from the glabella above the root of the pinna to the external occipital protuberance with its centre midway between these points; this strip and its elastic thus form the base-line. The cursor is adjusted to pass over the centre of the defect. The distance of the cursor from the central point 00 is read off, and the height of the centre of the depression above the base-line. The circumference of the head and the breadth along the line of the cursor are recorded on the tapes, and the diameter of the gap is measured. To preserve a record, a radiograph is now taken with the following precautions to prevent distortion: (1) The tube is at least 2½ ft. (0.75 metre) from the patient's head; (2) the rays are centred on the central rivet; (3) a purely lateral radiograph is taken as shown by the line of dots being straight. If such measures are not taken the strangest effects are produced.

Since heads vary greatly in length and breadth these must be allowed for. Length is much the more important,

and must be corrected for, before the breadth. There is only one horizontal constant for length, and that is:

1. 
$$\frac{\text{Circumference of head in G.O. line of key}}{\text{Circumference of head in G.O. line of patient}}$$

When the distance of the cursor from the centre has been multiplied by this constant the corrected length (a) is marked on the key. The breadth of the skull varies at different points along the G.O. line, and is found by measuring the distance between the elastic and celluloid parts of the base-line along the line of the cursor. The breadth constant is:

2. 
$$\frac{\text{Breadth of skull at point (a) on key}}{\text{Breadth of skull at point (a) on patient}}$$

After determining this constant the height of the centre of the gap above the point (a) is recorded on the key and the area of the defect plotted out. (Mr. Mason has had prepared a number of prints of the key radiograph so that the corrected measurements can be transferred direct to it without the need of radiographing the patient's skull.)

The accuracy of the method was tested on cadavers as follows:

First, a number of match-sticks were sharpened and dyed. The centres of six important gyri were chosen—namely, the parietal, lower part and junction of lower third and upper two-thirds of pre-Rolandic gyrus, superior temporal, marginal, and angular gyri. The gyrometer having been placed in position on the cadaver's head, the constants for the breadth and length were determined. The heights of each of these gyri and the distance from the zero point at which their perpendiculars cut the base-line were measured on the key and corrected by multiplying by the constants. The points thus determined by the skull were marked on the scalp of the cadaver, and in these positions the skull was drilled with a gimlet and a coloured match-stick inserted until it entered the brain. The process was repeated on the other side. The brain was removed with the matches *in situ* and each was identified.

Thus in one case the circumference of the head was 24 in. As that of the key radiogram was 22.5 in. the constant for length was  $24/22.5 = 1.075$ , or practically 1.1. The breadth of the head opposite the angular gyrus was 11.5 in. and the corresponding breadth on the head used for the key radiogram was 11 in. This gives a vertical constant at this point of 1.05, which can be taken as unity for practical purposes. The angular gyrus on the key is 2.8 in. behind the central point and 2.5 in. above the base-line.

Multiplying these figures by their respective constants one obtains a point 3.1 in. behind the zero point and 2.5 above the base-line. This point should be over the angular gyrus of the cadaver. In no case was the discrepancy more than a quarter of an inch, and this could easily be accounted for by the variation in the pattern of the convolutions.

#### Superimposition of Defects.

Whilst a single craniotomy opening is too large for accurate localization, by this method superimposition of several areas in cases presenting identical symptoms will enable us to narrow down the supposed lesion.

#### Special Features.

1. Applicability to investigation on the unshaven head, the elastic serving to keep the gyrometer in close apposition to the head. Moreover, as has been stated, three-fourths of the base-line is hairless.
2. Ease with which the base-line is fixed.
3. The sharp picture of the cranial gap as shown by a radiogram as compared with the unconvincing results of a photograph.
4. Its suitability for the study of the much debated problem of the speech mechanism, since all the areas concerned—namely, the intermediate, precentral, supramarginal, and superior temporal convolutions—come within its limits.
5. Possibility of narrowing down the area affected by superimposition of several cases.

#### Clinical Material.

(a) Undoubtedly the best material for this method will be cases of depressed fractures. In the first place, the patients, whether civil or military, are healthy labourers or soldiers who have been injured at work or in the field. Their brains are not the nervous derelicts that Broca's cases were. Secondly, the injury is usually maximal on the surface, and therefore affects chiefly the grey matter and tends to be fairly localized. The war provided us with a mass of material; the men, as Head says, were intelligent and took great interest in their progress, unlike the nervous breakdowns one usually has to examine.

(b) Trephining for simple tumours, including cysts and granulomata, vary in value inversely as their size. If a note were made of the position of the tumour in relation to the gap, these cases would be of much greater use from the point of view of research.

#### Fallacies.

It must not be supposed that localization of function will be easy by this method; there are many pitfalls:

(a) The *bête noire* of this and all other methods save the anatomical ones is the presence or absence of subcortical injury. Broca's failure to recognize this has led to much confusion and provoked the classical argument of Pierre Marie.

(b) *Diaschisis*.—A small disturbance at one point is capable of producing widespread functional effects.

(c) The gyrus underlying the centre of a cranial defect may be a silent one or have been destroyed; or, again, the margins may have contracted adhesions to the bony rim, and this may be responsible for the symptoms.

(d) The decompression resulting from the trephining may have in itself caused the disappearance of symptoms regardless of the position of the injury or tumour.

(e) The absence of cortical injury does not exclude a subcortical one; even the opposite side of the brain may be affected by *contre-coup*.

To sum up, each case must be carefully weighed on its merits, and only after most careful sifting of the evidence is one justified in assuming that the brain underlying a cranial gap is the part responsible for the symptoms.

#### Localization of Tumours.

The first essential is to determine by a careful study of the signs and symptoms the probable position of the tumour in the cortex, since only these are capable of localization by the method here described. Mark the supposed site on the key radiogram, note its distance along the base-line from the point 00, and its height above that line. Note the circumference of the head and the breadth along the line of the supposed growth. However, except for children and individuals with particularly large or small heads, it is not necessary to correct by constants, since the accurate localization of tumours to less than half an inch is at present impossible. Apply the gyrometer to the head, and slide the cursor to the position marked on the key; then measure height up and mark with a scratch. This will form the centre of the subsequent trephining. It will always be advisable for the opening to be large, but it is very advisable for the tumour to be in the centre of it, so that should removal be impossible decompression is maximal over the site of greatest disturbance. Whilst a neurological surgeon can visualize the brain beneath the cranium with a fair degree of accuracy, this faculty only comes from long experience. This method when applied to tumours should be of service, first in giving us a better idea of cortical function, and secondly in enabling us to trephine more nearly over the site of the disturbance.

#### SUMMARY.

A. A method has been described of determining the gyrus underlying a cranial defect by means of clinical measurements and a key radiogram.

B. Aphasia can be satisfactorily studied, since the parts presiding over the speech mechanism are within its range.

C. Trephining for tumours may be done more nearly over their position once they have been localized clinically.

D. With a long series of cases of trephining accompanied by pre- or post-operative symptoms it is hoped to confirm and revise our knowledge of cortical function, especially as regards aphasia, so that tumours may be explored with greater certainty.

The author's best thanks are due to Professor Elliot Smith, Mr. Harris, and Mr. Melville, of University College, for their generous assistance in the preparation of the key radiogram.

#### GENERAL DISCUSSION.

Mr. GEOFFREY JEFFERSON (Manchester) said that he proposed to confine himself to generalities rather than to particularize on any single aspect of this wide problem. It was extraordinary how interested surgeons in general

were in operations upon the nervous system. Yet he would point out that while it was not very difficult to attain proficiency in skull surgery, in the removal of bone, or in cutting flaps, when it came to brain surgery the matter was not so simple. There were many good bone surgeons, but in all the world there were very few who excelled in dealing with brain tumours. In some degree this was a remediable state of affairs, as the cure lay in more intensive work in that field. He was not convinced that pure specialization was practicable, for though it was the ideal theoretically, the work was physically so tiring, and mentally so exacting, that a holiday, as it were, in other fields was desirable. Here, as elsewhere, it was essential that the neurological surgeon should graduate through general work. One of the chief interests in brain surgery came from the fact that it was so far from perfection. In tumours of the breast the precise site of the growth and its pathology were usually known, the type of operation could be easily determined, and the future course of the case could be estimated with some confidence. How different was the picture in brain tumours! No rapid advance was to be expected, save by working on large masses of material and this material was there if it could be recognized early and brought to the surgeon. In the past there had been a too widespread belief, first, that cerebral tumours scarcely ever occurred; secondly, that they could not be recognized if they did occur; and thirdly, that nothing could be done for them if they were recognized. They were, as a profession beginning to realize that brain tumours in their various forms were common. His personal experience during six years amounted to 55 cases, of which for various reasons 38 had been operated upon. Some of the patients had been refused operation: among these were one patient with pituitary tumour who was blind, and several comatose patients with gliomatous tumours. The purely decompressive operation had lost the pre-eminent position it had held as an end in itself. At the present time an attempt was almost invariably made to deal primarily with the tumour, the decompressive part having become subsidiary. No good was likely to be done in the last stages of compression. The pressure rendered an attack on the tumour difficult and most hazardous, and the case did not react favourably to decompression. In these conditions hypertonic intravenous saline was the method of choice; it sometimes acted almost miraculously in withdrawing patients from danger.

Mr. J. P. Ross (London) said that only an early diagnosis brought the patient under surgical treatment at a period in the disease when that treatment was most likely to have a good effect. At the onset, and in the early stages of the disease, the symptoms and signs were frequently indefinite, and there was often little to arouse suspicion. Yet it was only by remembering that cerebral tumours were not as rare as was frequently supposed, and by suspecting the possibility in every case of repeated severe headache, of palsy, or involuntary movement, and of sensory disturbance or mental alteration, that an early diagnosis could be made. He instanced the case of a boy of 16 who complained only of his left knee; a complete examination of his central nervous system led to surgical operation and the discovery of a cerebral tumour. Familiarity with the ophthalmoscope and a certain degree of skill in its use should be the possession of every practitioner, because ophthalmoscopic examination would often prevent further loss of time in cases which had passed the earliest stage of disease. He thought that the surgeon interested in the treatment of brain tumour should have a training in neurology sufficient to enable him to localize the lesion when possible, though it would usually be desirable to collaborate with a neurological colleague in this investigation. While ventriculography might prove of the utmost value in many cases it should only be used when all the possibilities of physical examination had been exhausted. The surgeon should also be familiar with the pathology and the natural history of the various tumours, so as to be able to give a fairly accurate guess as to the nature of the neoplasm with which he was dealing; for his operative procedure might be considerably modified by his opinion on this aspect of the problem. The surgeon should hold himself

responsible for the diagnosis of the lesion and the decision as to its treatment.

With regard to the operation, he believed that an attempt at surgical relief with the possibility of cure should always be made, however desperate the case might at first appear, with the exception of certain tumours which could be accurately localized in inaccessible situations and cases of metastases in the brain. It was known that over 40 per cent. of cerebral tumours were gliomatous in nature, and of these comparatively few could be extirpated, even at the earliest period at which they could be diagnosed; it was clear that a very large proportion of advanced cases would prove to be hopeless whatever treatment was adopted. Nevertheless operative treatment was justified. When there was great intracranial tension an attempt should be made to lower the pressure within the skull before opening the dura, either by withdrawing the fluid from the lateral ventricle or from a cyst if present; by infusion of hypertonic saline solution; or, if these failed, by lumbar puncture, everything being in readiness to open the dura should untoward symptoms appear. When the tumour was beneath the tentorium it was necessary, and usually easy, to tap the lateral ventricle to relieve pressure, but when the tumour lay in the substance of one of the hemispheres the ventricle might be much diminished in size, greatly displaced, or completely obliterated, and it might be impossible to use this method. He believed it of great importance, when fluid was obtained by puncture of the brain, that it should be allowed to escape very slowly, for if it escaped rapidly and the tension were quickly reduced, the oedema which always resulted from this reduction in pressure was correspondingly greater in degree and extent. The cerebral oedema which followed decompression was believed to account for an appreciable post-operative mortality, and any measures which tended to prevent its occurrence should be carefully considered and practised. He instanced the case of a woman admitted to St. Bartholomew's Hospital in a semiconscious condition, where the diagnosis was only made exactly by skiagrams showing the shadow of the calcified pineal body displaced to the right side. The left side of the skull was explored, and an attempt was made to tap the lateral ventricle. This failed, but a gliomatous cyst was discovered in the region of the motor cortex and the fluid was evacuated. The dura was then opened with safety, but the tumour was irremovable. Some hours after operation the patient showed signs of cerebral compression, but these disappeared after an intravenous injection of 70 c.cm. of 15 per cent. sodium chloride. Her condition greatly improved, and she was later given a course of x-ray treatment, focused on the growth; the improvement was only temporary, however. The speaker hoped that advance might be made in the future towards more radical treatment of gliomas, and that the tumour might be removed without causing so much damage that, though the patient's life was saved, yet it was scarcely worth living. The control of haemorrhage presented great difficulty, and the operative procedures would often have to be divided up into several stages. Local anaesthesia could often be used with advantage, especially for the preliminary stages; rectal and subcutaneous saline infusion and blood transfusion during the operation would enable the patient to stand surgical treatment, which could not be attempted without such aid. A record of the blood pressure and pulse rate throughout the operation was taken. He had repeatedly seen the pulse become steadier and the blood pressure rise when the patient, during the course of an operation, was given a rest for a few minutes. Two important causes of death after operation were oedema and haemorrhage. Oedema was to be combated by minimizing the amount of trauma to which the cerebral tissue was exposed, and by making the process of reduction of intracranial tension as gradual as possible. Hypertonic saline solution was used to control symptoms of cerebral compression appearing after operation, but when this failed, and further decompression was called for without delay, he had seen good results follow enlargement of the decompression opening left in the base of the flap of osteoplastic resections, or, in the worst cases, complete removal of the bone from the flap. Haemorrhage was not a frequent cause of post-operative trouble when care had been taken to arrest

all bleeding before closing the wound, but when, despite all precautions, signs of bleeding appeared, the wound should be reopened without hesitation, the clot removed, bleeding points dealt with, and the wound closed once more. Sometimes post-operative rise in intracranial tension was due to the refilling of a cyst tapped at operation, and in cerebellar operations there might still be hydrocephalus present. Before reopening the wound an attempt should be made to reduce the intracranial pressure by tapping either the cyst or the ventricle, by introducing a lumbar puncture needle through the hole made in the bone at operation.

Very little was known of the value of radium and x rays in the treatment of intracranial tumours. He had seen several cases of inoperable glioma benefit by x-ray treatment, while others appeared to be unaffected. In one case where a portion of the tumour was removed for histological proof, subsequent x-ray treatment enabled the patient to return to work. She did well for a year, when she was knocked down in the street and died as the result of the accident. At the necropsy it was found that almost the entire tumour had been converted into a structureless mass, which was infiltrated with leucocytes and was apparently undergoing absorption, although there was still some active growth at one point. He attributed the various results obtained by radiation of the gliomata to the several varieties of this tumour which were believed to exist.

Professor R. E. KELLY (Liverpool) called attention to the slight changes in the inner table of the skull sometimes caused by endotheliomata. There was a curious roughening of the inner table, exactly corresponding with the underlying tumour, which might be a determining factor in its localization.

Dr. A. GURNEY YATES (Sheffield) wished to reinforce what had already been said about the importance of early diagnosis, but thought that it should be remembered that slight localizing signs might occur in the early stages and be masked ultimately by the increasing intracranial pressure. It was therefore, in many cases, not desirable to wait for the development of further localizing signs. He illustrated his point by reference to a recent case of cerebellar tumour under his care.

Mr. PERCY SARGENT, in reply, said that x rays were sometimes useful in the diagnosis of a tumour of the brain, therefore it was a method of diagnosis which should be used. Calcified gliomata might be revealed in this way. Very often there was a history of trauma in tumour of the brain, but if careful inquiry was made, almost anybody, at some time or other, would be found to have had a blow on the skull, and therefore too much importance should not be attributed to the injury, and its importance as the causative agent could not be accurately estimated. He agreed that the effect of increasing general pressure might be to mask localizing signs. He also referred to false localizing signs, first called attention to by Victor Horsley.

## PERFORATION AND RUPTURE OF THE GALL BLADDER.

BY

LIONEL R. FIFIELD, F.R.C.S. Eng.,

SURGICAL REGISTRAR AND FIRST ASSISTANT, LONDON HOSPITAL.

THIS paper is based on 28 cases of perforation or rupture of the gall bladder which have occurred during the last twenty-five years at the London Hospital. In that period there have been in the surgical wards 520 cases of cholecystitis with gall stones (80 acute, 65 chronic, and 374 unclassified) and 546 (73 acute, 87 chronic, and 386 unclassified) without them—1,066 cases in all.

Rupture of the gall bladder may result from violence, such as a blow on the abdomen or a run-over accident, but is a very uncommon occurrence and less frequent than rupture of the bile ducts. One only of the present series of cases was due to this cause.

A youth, aged 22, was run over by a cart. He was treated expectantly and apparently completely recovered from the accident. Two months later he visited his doctor, complaining of a

gradual increase in the size of his abdomen. He was not jaundiced. Laparotomy was performed by Mr. Hutchinson and an enormous collection of bile found in the subhepatic pouch, the right anterior subphrenic space, and the right lumbar fossa. In the remaining part of the peritoneal cavity (which was shut off by adhesions) was a large quantity of serous fluid. The hole in the gall bladder was sutured and the subhepatic fossa and pouch of Douglas drained. The patient made an uninterrupted recovery.

Perforation or rupture results much more frequently from ulcerative cholecystitis, generally associated with the presence of gall stones. In this series 27 cases were due to ulcerative cholecystitis, and in 26 of them gall stones were present. The remaining case, was, perhaps, sufficiently interesting to be recorded in more detail.

A man, aged 38, was suddenly seized with severe upper abdominal pain, fell down and could not move. He vomited twice; the abdomen was "board-like." The diagnosis of perforation of a gastric ulcer was made (he had a two months' history of indigestion of the gastric ulcer type). Laparotomy was performed and a perforated gangrenous gall bladder found. No gall stones were present. Drainage of the gall bladder and subhepatic pouch was provided for, and the patient made an uninterrupted recovery.

Mitman reported a case of chronic pancreatitis with rupture of the gall bladder following ulceration near Hartmann's pouch, and thought that straining at stool precipitated the catastrophe. No history of strain or injury, however, could be obtained in the great majority of the present series of cases. Nordentoft recorded a case of perforation in a paratyphoid carrier with acute cholecystitis (no calculi), and cases of perforative cholecystitis during typhoid fever have been placed on record.

#### AGE INCIDENCE.

One patient, the traumatic case already reported, was 22 years of age; 4 were between 30 and 39; 5 were between 40 and 49; 6 between 50 and 59; 6 between 60 and 69; and 6 between 70 and 79. Sixteen of the patients were women, and 12 (including the traumatic case) were men.

#### DIAGNOSIS.

Diagnosis was often very difficult. In 4 cases the diagnosis of acute intestinal obstruction was made, there being absolute constipation, colicky abdominal pain and vomiting, and some distension; 3 patients were thought to be suffering from perforation of a gastric or duodenal ulcer (2 gastric, 1 duodenal); they were suddenly seized with agonizing upper abdominal pain, vomited, and were in a condition of shock when seen, the abdomen being board-like in its rigidity. One of these patients actually fell down in the street, so sudden in onset and severe was the pain. The diagnosis of a high appendix abscess was made in 2 cases in which an abscess had resulted from perforation of the gall bladder. In just over a third of the cases acute cholecystitis was diagnosed, and in the remainder (which included the very late and moribund) diffuse peritonitis of unknown origin. Slight jaundice was present in 5 cases, of which 4 were suffering from diffuse peritonitis and one from abscess formation. From only 8 of the patients could a history of flatulent dyspepsia or biliary colic, with or without jaundice, be obtained.

#### CONDITION FOUND AT OPERATION.

In early cases (4) bile and sometimes calculi were present within the peritoneal cavity; in later cases (15) diffuse peritonitis was present, while in others a localized abscess had resulted in the subhepatic pouch (10 cases, 2 of which are also included in the 15 cases of diffuse peritonitis). Diffuse peritonitis, therefore, was found in the majority of the cases—15 out of 28. The gall bladder was in a condition of suppurative or gangrenous cholecystitis and a perforation present, most commonly near the fundus. Almost as frequently it was situated at Hartmann's pouch or midway between the two. The perforation varied in length from a quarter of an inch to an inch and a half, and bile or pus and calculi were generally to be seen escaping through it. In 2 cases the gall bladder was found only with the greatest difficulty, and in 2 others was not seen at all, dense adhesions and the poor condition of the patient contra-indicating further search. Extensive fat necrosis was

present in 2 cases, but in one of these the patient also had acute pancreatitis. One case of subhepatic abscess resulting from perforation of the gall bladder was complicated by fistulae leading from the abscess cavity into the colon and duodenum.

In Gjellerup's case there was a haemoperitoneum of 2 pints. Sussig and Hörnhammer reported 2 cases of extraperitoneal perforation; Wendel recorded an extremely interesting case of torsion of the gall bladder with perforation and calculi lying free in the resulting abscess cavity. The gall bladder was not gangrenous, although the cystic duct and vessels had rotated completely several times. Schweizer reported a case of perforation of the gall bladder with fat necrosis.

#### TREATMENT.

Treatment depended on several factors, especially the condition of the patient and the condition found at operation. Cholecystectomy was performed in 5 cases—one with diffuse peritonitis, 2 with abscess formation, and 2 soon after perforation. The first died, the second two recovered, and one of the last two died. The remainder were treated by drainage of the gall bladder and subhepatic pouch; suprapubic drainage was added if diffuse peritonitis was present. Summarized, the treatment is generally drainage of the gall bladder by a tube inserted through the perforation and drainage of the subhepatic pouch. Suprapubic drainage is sometimes necessary. Cholecystectomy may be performed if the patient's general condition and the local condition of the gall bladder and surrounding tissues do not contraindicate it.

#### PROGNOSIS.

Of the 4 patients operated upon soon after perforation 3 recovered and one died of shock; 7 of the 8 cases in which an abscess had formed recovered, one died. Fifteen patients were suffering from diffuse peritonitis; 10 died (2 had localized abscesses in addition) and 5 recovered.

It will be seen, therefore, that when operation was performed soon after rupture, or when an abscess had formed, prognosis was good, 10 out of 12 recovering. On the other hand, when diffuse peritonitis was present the prognosis was poor, 10 out of 15 dying.

In cases of rupture due to violence the prognosis depends upon concomitant injury to other viscera, the presence of infection in the gall bladder, and the time elapsing between the accident and operation. If the bile be sterile the last factor is of less importance.

In the present series only one was the result of violence, and he recovered, although operation was performed two months after the rupture had occurred.

I wish to thank the surgical staff of the London Hospital for permission to include in this series cases which were under their supervision, and especially Mr. Hugh Lett for some helpful suggestions.

## A CASE OF SARCOMA OF THE LUNG.

BY

R. ALLAN BENNETT, M.D.LOND., M.R.C.P.,

PANAMA.

THE case here reported is no exception to the rule that tumours of the lungs are difficult to diagnose; had it not been for the metastases it would have been impossible to be dogmatic about it.

A woman, aged 47, had been out of sorts for two months, with no symptoms except shortness of breath on slight exertion. She had been operated upon twenty years before for tuberculous glands in the neck, and her family history was tainted with tubercle on both sides. She looked ill, but repeated examinations revealed no abnormal signs of any sort. The blood count gave 4,800,000 red cells, 11,000 white cells, and the differential count was normal. No diagnosis was made.

A fortnight later she woke in the night with great dyspnoea; the whole of the right chest behind was found to be dull and the breath sounds were absent, while in front there was an area, extending from the apex of the lung to the level of the fourth rib, where the note was tympanitic, the vesicular murmur absent, and the voice sounds were loud and close to the ear. Below this there was dullness and the breath sounds were absent. Vocal fremitus was absent over the whole side, back and front. The apex beat was not displaced; the heart sounds were feeble and the pulse varied from 90 to 110. A needle withdrew clear coloured fluid, and on aspirating the chest 16 ounces were removed, blood-stained towards the last.

The removal of this fluid made no difference to the physical signs, and did nothing to relieve the dyspnoea of the patient, which was now severe, and threatened to be fatal. After some hours the symptoms abated, and on the following day the patient was little the worse for her experience, though any movement brought on distressing shortness of breath. Examination of the fluid then and subsequently removed from the chest showed a small predominance of mononuclear leucocytes, and injection on two occasions into guinea-pigs did not affect the animals.

The temperature did not rise above 100° for the first three days, but on the fourth there was a rigor, and for the rest of the illness there was a daily variation of several degrees (97° to 104°), without much sweating. In spite of this the patient improved, and by the end of the second week she could move about with comfort. There was no cough, the physical signs did not alter, the blood count was the same, and it was thought then that the condition was a pneumothorax of tuberculous origin.

On the twenty-eighth day the patient, lying quiet in bed, cried out that she was suffocating, and an attack followed, very like that already described. This time it seemed impossible that she could rally, but in the course of four hours the symptoms subsided and she was in comparative comfort.

Not until 12 ounces of blood-stained fluid had been withdrawn from the chest was there any change in the physical signs. There was then over the whole of the right lower lobe behind a tympanitic note, with distant loud bronchial breathing, like that heard over the trachea when compressed. This sound, to which the name "corragé" was given by Behier fifty years ago, is said to be pathognomonic of bronchial obstruction, and if heard over the root of the lung and accompanied by dullness, of tumour. Though the sign in this case did not fulfil these two conditions, it was a striking phenomenon, occurring so suddenly over a wide area previously silent, and its appearance threw the first doubt upon the diagnosis already made. The condition of the patient during the next three weeks became steadily worse; the dyspnoea increased, and though the chest was aspirated twice only 9 ounces of fluid were taken away on each occasion, and the removal did not alter the physical signs. The blood examination showed an increasing anaemia: the red cells at the end of the fifth week of the illness numbered 3,980,000, the white cells kept between ten and twelve thousand, and the differential count remained normal. The temperature was hectic. There was little cough and no expectoration.

On the fifty-eighth day the patient complained of pain over the front of the chest, and a nodule the size of a pea was found at the junction of the fifth right costal cartilage and the sternum. It was extremely tender, movable under the skin, and apparently fibrous. It was excised, and the report on its structure cleared up any doubt as to the nature of the disease; it was described as a small round-cell, deeply pigmented sarcoma. Other nodules appeared at intervals in the skin of the right chest, and added greatly to the misery of the patient; they were all tender, and some of them were the starting-points of acute neuralgic pains, which spread over wide areas of skin.

Two more attacks of acute dyspnoea occurred—one on the seventieth, the other on the seventy-fourth day—with no change in the physical signs. On the eighty-seventh day, three months from the date of the first examination, the patient had an enormous haemoptysis and died at once. A post-mortem examination was not allowed.

In the discussions that arose over the differential diagnosis the question of primary malignant disease of the lung and pleura arose more than once, but it did not seem to those who listened to the chest that there was any justification for abandoning the diagnosis already made. It might

be said that the persistence of blood in the aspirated fluid should have been allowed more weight in the decision, but there are simpler explanations of this than malignant disease of the lung, and it was possible to point to one positive sign only—the predominance of the mononuclear leucocytes. An x-ray examination of the chest, which might have given the diagnosis earlier, was impossible, as the patient lived in a remote district of West Africa, seventy miles from an apparatus.

I have found in the literature only one example of sarcoma of the lung with secondary deposits in the skin—a case published by Peritz of Berlin in 1896, where metastases occurred in the mediastinal and cervical glands, the spleen, the liver, and both kidneys.

## PERSISTENCE OF TUBERCLE BACILLI IN BUTTER FROM TUBERCULOUS MILK.

BY

H. A. COOKSON, M.B., CH.B., F.R.C.S.,

D.P.H.,

PATHOLOGIST, ROYAL INFIRMARY, SUNDERLAND; BACTERIOLOGIST, SUNDERLAND HEALTH AUTHORITY.

THE danger arising from the presence of tubercle bacilli in butter has not attracted in this country the attention it deserves, though probably fresh butter containing these bacilli is not infrequently on sale. With a view to determining their persistence in butter made from milk known to contain them, specimens of milk were collected from five tuberculous cows; three of these cows were afterwards shown to have extensive tuberculous lesions, and in all five cases the presence of tubercle bacilli in the milk was demonstrated by inoculation into guinea-pigs.

From these five milks butter was made by naturally ripening them without heat, other specimens being pasteurized at 55°, 60°, and 70° C.; after this heating butter was made by using a "starter" to produce artificial ripening. The various specimens of butter were melted and kept at 40° C., sedimentation being allowed; the difficulty of satisfactorily centrifugalizing butter samples was to some extent overcome in this way. From the melted samples in cylindrical containers 4 c.cm. was taken from the surface and another 4 c.cm. from the bottom, guinea-pigs being inoculated with the total 8 c.cm. When the milk was pasteurized it was heated in a container at one of three temperatures—55°, 60°, and 70° C.—the samples of milk being maintained at the selected temperature for thirty minutes, and continuously stirred while the thermometer readings were carefully watched.

The proof that tubercle bacilli caused the lesions found in the guinea-pigs was afforded by histological examination of the affected glands. Smears of the gland pulp were stained for tubercle bacilli, prolonged treatment with sulphuric acid being followed by the application of alcohol for ten minutes. To ensure the elimination of error due to the presence of acid-fast butter bacilli cultures were made; the rate of growth of the colonies and morphological considerations gave further confirmation of their identity.

The five specimens of milk were all shown to contain tubercle bacilli. One sample of butter made from naturally ripened milk was found to contain tubercle bacilli; the butter produced in other ways from this milk was also found to be similarly infected. The other four samples of milk, whether unheated or heated, produced butter which was free from tubercle bacilli. For the various examinations twenty-five guinea-pigs were used.

It would therefore appear that even the most careful pasteurization is not always a sufficient protection against the survival of tubercle bacilli. Work is now proceeding to determine the time of persistence of live and virulent tubercle bacilli in butter after it has been stored in the ice-chest, both salted and unsalted preparations being used. The present series of experiments is too small to allow definite conclusions to be drawn, but the importance of the point at issue seems to justify the publication of this preliminary report.

**Memoranda:****MEDICAL, SURGICAL, OBSTETRICAL.****AN UNUSUAL OBTURATOR HERNIA.**

An obturator hernia is comparatively rare, and it is seldom possible to diagnose it before operation, which is generally undertaken on account of acute intestinal obstruction. The following case is of interest in that there was a palpable swelling which enabled a correct diagnosis to be made. This swelling was the result of spread of inflammation beyond the sac wall, due to the nature of the contents of the sac.

Mrs. D., aged 51, a patient of Dr. Kempson Brown of Ludham, was seized with severe pain in the right groin on April 17th, 1926. For a week the pain remained severe and it spread down the thigh and into the knee. During this time her bowels were opened two or three times. She vomited once after taking salts.

I saw her on April 24th. She was a stout woman, difficult to examine. Her general condition was good. There was nothing abnormal to be made out in the abdomen. Deep in the upper and inner part of the right thigh, 2 inches below the pubic spine, was a fixed tender swelling about the size of a pigeon's egg. It could be palpated more easily with the hip flexed.

Per vaginam a tense swelling could be felt, fixed to the right wall of the pelvis at the level of the upper border of the obturator foramen. She was admitted into the Norfolk and Norwich Hospital, and the operation was performed on April 25th. A vertical incision was made below the right pubic spine. There was brawny induration of the adductor longus and pectineus. A small thickened sac over the obturator canal was exposed. The sac was incised and pus escaped. (The pus was negative on being cultured.)

Right paramedial coeliotomy was then performed. The right Fallopian tube was found entering the obturator canal. The tube was withdrawn from the canal after freeing adhesions between it and the sac wall. The tube was thickened and distended with pus, and was excised. The right ovary was not involved in the hernia and was not removed.

The abdominal wound was closed and a cigarette drain inserted into the wound in the thigh. The latter suppurated freely, but except for this she made an uneventful recovery and left the hospital on May 27th.

It may be of interest to add that the patient's husband has suffered also from an unusual form of hernia. I operated on him five years ago for acute intestinal obstruction of twenty-four hours' duration. He had worn a left inguinal truss, but there was no swelling to be felt in either inguinal canal. A laparotomy was performed and a loop of small bowel was found strangulated in a diverticulum of a left inguinal hernia which extended upwards between the left rectus muscle and the peritoneum of the anterior abdominal wall—the properitoneal variety of an interstitial hernia. I may say that at the present time he has a hernia which is only too evident when he removes his truss.

A. J. BLAXLAND, M.S., F.R.C.S.,  
Surgeon, Norfolk and Norwich Hospital.

**CARDIAC PAIN IN PERNICIOUS ANAEMIA.**

DR. CAREY COOMBS's note on cardiac pain in pernicious anaemia (July 31st, p. 185) recalled to my mind an instance in which the symptoms of precordial pain and shortness of breath overshadowed for a time the underlying condition of anaemia.

A man, aged 48, came to see me in regard to attacks of pain over the heart, which occurred frequently after he had finished his day's work; on resting after his evening meal the pain lessened in severity. His only other symptom was slight shortness of breath on exertion. He was a healthy looking man, and had suffered his pain for nearly a year before seeking advice. No cardiac murmur was heard, but the heart was slightly hypertrophied. After about a month's treatment he improved in health, and I did not see him again for three months. The shortness of breath had then returned, and he looked paler than on his former visits to me. On this occasion no further signs were evident in the heart, but his right foot was rather puffy about the ankle. I now tested his blood, and found that the red cell count was down to three and a half millions. His colour index was 1.2, and the blood film showed the typical picture of pernicious anaemia. His blood pressure was normal for a man of his age.

He was now put on prolonged treatment and lived for four years. During this period, however, he had a number of attacks of severe precordial pain, some of which closely resembled angina pectoris.

This case resembles some of those Dr. Carey Coombs cites in his article, but the evidence of cardio-sclerosis was

only slight. My object, however, in recording the case is to show that, as in his series of cases, the evidence of cardiac disease overshadowed the true nature of the condition.

Fochriw, Glam.

T. STENNER EVANS, M.B., B.S.Lond.

**SUDDEN DEATH DUE TO ACUTE HAEMORRHAGIC PANCREATITIS.**

THE following details of a somewhat unusual case—namely, the sudden death of a man aged 29 from acute haemorrhagic pancreatitis, may be of sufficient interest to merit publication.

The patient had been in his usual health until the day of his death, when he suffered from slight diarrhoea, which did not prevent him from playing cricket during the greater part of the afternoon. He was suddenly attacked by faintness and severe epigastric pain without vomiting or cyanosis. He recovered sufficiently to enter a car, but a few minutes later he died suddenly.

At the necropsy the pancreas was found to be densely infiltrated with blood throughout its whole extent. There was no free fluid in the peritoneum, and no evidence of fat necrosis. The gall bladder and biliary passages were normal, with no signs of calculi or of inflammation. The lower end of the ileum, however, was inflamed, although the caecum and appendix were not affected. The heart, kidneys, brain, and other organs were all normal.

This case appears to be one of the rare group described by Mayo-Robson as "ultra-acute," or "pancreatic apoplexy," the characteristic points being the violent and sudden onset, accompanied by collapse, and ending fatally, with extreme rapidity. In view of the work of Deaver and Ashurst on the spread of infection to the pancreas via the lymphatics, the inflamed condition of the lower end of the ileum may have had some etiological association with the fatal pancreatitis.

A. C. MACONIE, M.B.Lond., F.R.C.S.Eng.

Shanghai.

**A LOCAL ANAESTHETIC FOR THE EAR.**

AFTER many years of disappointing experiment I have found a local anaesthetic mixture which is of real service to the otologist. It consists of equal parts of cocaine hydrochloride, menthol, crystallized carbolic acid, rectified spirits, and oil of cloves. I claim no originality for the prescription, because I read of it, or something very like it, in a foreign journal, either French or American, a year or more ago.

A cotton mop wet with the fluid is placed against the drumhead and left for ten minutes. At the end of that time anaesthesia is satisfactory. I have many times performed paracentesis in cases with acute trouble, and the anaesthesia has been perfect. I have several times cut away the post-malleolar drumhead to get attic drainage. Recently I removed the whole of a retracted drum, adherent to the promontory, from a nervous female patient. She felt no pain whatever. The one disadvantage of this otherwise perfect solution is its liability to set up otitis externa if it is permitted to touch the walls of the external meatus. To get over this difficulty I have tried leaving out the oil of cloves, but without this ingredient it has proved useless. I explain its great efficiency on the supposition that the oil of cloves penetrates the tympanic membrane and carries the anaesthetic drugs deep into the middle ear.

F. PEARCE STURM, M.Ch.

Ear and Throat Clinic, Leigh, Lancs.

**ADRENALINE IN CARDIAC ARREST.**

WITH reference to Dr. Livingston's case of resuscitation in an infant during anaesthetic collapse (August 28th, p. 388), I also have tried the same treatment on four different occasions on infants apparently stillborn and who did not respond to the ordinary methods of restoring animation. In three cases the infants responded at once and have since remained healthy. In the fourth case there was no attempt to breathe.

Oldham.

MARY G. CARDWELL, M.D.

## Reichert.

### INTRACRANIAL PHYSIOLOGY AND SURGERY.

Dr. HARVEY's Cushing's Cameron Lectures have lately appeared in one volume under the title of *Studies in Intracranial Physiology and Surgery*,<sup>1</sup> the three lectures being devoted to the third circulation and its channels, to the pituitary gland, and to intracranial tumours. On such subjects the author can write as a distinguished authority whose opinions will receive careful consideration.

The first lecture deals with the cerebro-spinal fluid and its circulation. Here the author has wisely adopted the historical method of approach to problems which he himself and his fellow workers have done so much to elucidate. Beginning with the study of hydrocephalus, he traces the various investigations, clinical and experimental, which have yielded us our present knowledge. The now well known work of Weed on the absorption of the cerebro-spinal fluid by the arachnoid villi is clearly described, and full recognition is given to the same worker's valuable researches on the changes in the volume of the brain which follow the intravenous injection of hypertonic and hypotonic fluids.

An interesting discussion is that on the phagocytic properties of what the author terms the meningoectes, certain cells of the arachnoid membrane which, besides their phagocytic powers, possess very active regenerative properties, well seen in the formation of new membranes after surgical interventions. To these cells also is attributed the power of forming bile pigments from blood, a character which seems to place them amongst those belonging to the system known as the reticulo-endothelial. A further practical importance is attached to these cells by the suggestion that it is from them that the tumours now widely known as the meningiomas (after the author's terminology) arise.

The advantages of the historical method are again well seen in the second lecture on the pituitary gland. A brief but masterly sketch of the earlier work of the author and others prepares the reader for a more detailed description of the various points of interest and importance in the histology, the physiology, and the clinical disorders of the pituitary body. The last section of this lecture is devoted to the more purely surgical aspects of the subject, where much of great practical value appears. In this short lecture Dr. Cushing has succeeded in giving a fascinating account of a subject whose literature is now enormous; the reader may congratulate himself that the subject is presented by one who has an unrivalled right to speak with authority and who can assist him to separate truth from mere hypothesis.

The final lecture, headed "Intracranial tumours and the surgeon," is less academic perhaps but none the less valuable. Its scientific interest lies principally in the account of the very elaborate and careful histological studies of the gliomas which have been undertaken by the author and his co-workers.

### A THEORY OF BONE.

THE multifarious lesions of bone constitute one of the obscure regions of pathology, and in view of the complicated nature of the subject we have become accustomed to accept the present orthodox and stereotyped teaching for better or worse, with a full consciousness of its insufficiency and in the hope of future enlightenment. There are few books that give much promise of realizing our expectations in this respect, but among these one, the normal and pathological physiology of bone,<sup>2</sup> by Professors LERICHE of Strasbourg and POLICARD of Lyons, undoubtedly gives the impression of having lightened our darkness to some extent.

The authors have divested themselves of preconceived ideas and started with a clean slate; they have made a ten years' study of every available bone lesion; have faced every difficulty of interpretation fairly and squarely; and have built up a new theory of the development, evolution, disease and degeneration of osseous tissue; which, they claim, is of universal application in the interpretation of the pathology of bone. Their theory is thus the product of their own observations and deductions, while they are careful to give full credit to previous observers for facts that are consistent with their teaching. The theory is based on the original conception of Reichert that bone is merely one of the various forms of connective tissue, of which other familiar forms are areolar tissue, tendinous tissue, mucous tissue, and cartilage, and can under varying chemical and mechanical influences pass from one form to another by a process which is usually designated "metaplasia." The authors point out that there is no essential difference between ossification in cartilage and ossification in membrane; the former is complicated by a preliminary process of absorption of cartilage, and ossification in membrane, being the simpler process, forms the basis of their research.

Their theory of osteogenesis is as follows: The connective tissue that is to undergo conversion becomes oedematous and exhibits a redifferentiation into an embryonic form by the proliferation of its fibrillae or fibroglia; the inter-fibrillar oedema is next replaced by or transformed into a viscid, semisolid substance, and to the altered tissue in this stage the authors have given the name of "pre-osseous," otherwise called "osteoid." Finally, a deposit of lime salts in the pre-osseous tissue completes the process, the deposit resulting probably from an alteration in the equilibrium of the calcium and phosphate ions in the fluids of the part, in the presence of a surcharge of calcium salts in the area of ossification. To produce such a surcharge, however, there must be a supply of calcium salts in the neighbourhood to be drawn upon; if the ossification is taking place in the neighbourhood of pre-existing bone the excess of calcium is derived from this, for the authors hold that the process of ossification is always accompanied by rarefaction and partial absorption of the surrounding osseous tissue; heterotopic ossification, on the other hand, they consider only occurs in association with lesions which themselves lead to a deposit of lime salts. With regard to the osteoblasts, the authors consider that they are not bone-producers, but have the same function as osteoclasts—that is, they absorb bone, and in this respect play an important part in rendering the locally existing lime salts soluble and producing the surcharge requisite in osteogenesis. The authors show how readily their theory explains many of the phenomena of bone disease, and if it is true it will prove an undoubted boon to pathologists.

### MUSCLE PHYSIOLOGY.

THE encyclopaedic scale of the textbook of normal and pathological physiology<sup>3</sup> is indicated by the fact that the first portion of the first half of the eighth volume consists of a large octavo book of 654 pages. It deals with protoplasmic movement and muscle physiology, and the articles it contains have been contributed by nearly twenty different authors.

We may state at once that the work is of quite exceptional interest and quality, for the subject of muscle physiology is one in which many important advances have recently been made, and the contributors to this volume include many of the persons chiefly responsible for these advances.

The advance of any science is not a continuous process; there are usually one or two fields in which it is particularly rapid. The physiology of muscle is a subject in which a rapid advance has been achieved in the last decade, and for this reason a series of authoritative monographs such as are contained in the volume under review is of particular value.

<sup>1</sup> *Studies in Intracranial Physiology and Surgery*. By Harvey Cushing, M.D. The Edinburgh Cameron Prize Lectures. Oxford Medical Publications. London: H. Milford, Oxford University Press 1926. (6 x 9½, pp. xii + 146; 16 figures. Paper cover. 8s. 6d. net; cloth 10s. 6d. net.)

<sup>2</sup> *Les Fondements de la Physiologie Normale et Pathologique de l'Os*. Par R. Leriche et A. Policard. Paris: Masson et Cie. 1926. (Med. 8vo, pp. 230; 33 figures. 28 fr.)

<sup>3</sup> *Handbuch der Normalen* ... herausgegeben von A. Berthel, G. Acher, Band, Erster Hälfte, *Ernergie*. Berlin: J. Springer 1926. 135 figures. G.M. 45; bound, 100.00

*ologie*. Herausgegeben von A. Ellinger. *Mechanische* pp. x + 654;

An inherent disadvantage of a rapid advance in any subject is that most of the literature becomes out of date soon after it is written. A highly specialized and difficult technique usually is developed and the subject attracts a large number of investigators whose work is often of very unequal value. Consequently only those persons who have a first-hand knowledge of the most recent methods of research can appraise the value of the work done.

The names of the authors contributing to the volume under review are indeed sufficient to indicate the high quality of their contributions. Professor O. Meyerhof, the Nobel prizeman, contributes three chapters on the respiration of muscles, the thermodynamics of muscle, and the theory of muscular activity. As he observes, these three subjects are really parts of a single big problem. The evidence available has been provided by means of extraordinary refinements in chemical and physical methods. The author discusses the oxygen consumption of muscles *in situ*, and this portion of his essay deals especially with metabolism experiments upon animals and men at rest and at work. He next discusses the oxygen consumption of excised muscles, and finally the theories of cell oxidations. In the section on the thermodynamics of muscle the evidence is detailed that has been obtained from the refined methods of calorimetry, by means of which it has been possible to analyse the various stages of heat production in muscle.

The article by Professor G. Embden on the chemistry of muscular contraction is another contribution of outstanding interest. He gives a full account of the complex process by which glycogen is converted to lactic acid, and this substance then partly oxidized and partly reconverted to glycogen. Other noteworthy articles are those by Professor W. O. Fenn on the mechanical properties of muscle and the time relations of muscular contraction, and those by Professor O. Riesser on the tonus of muscle.

The chief impression gained by reading the volume is the extraordinary amount of attention that has recently been devoted to muscle physiology. The articles deal with a dozen different aspects of the subject, and in all cases the majority of the references are to work done during the last decade, and in every article there are numerous allusions to work that is still unpublished.

Another remarkable fact is that nearly all this work has been done on skeletal muscle, and in only a few instances is any account given of the application of the newer and more refined methods of investigation to cardiac and plain muscle. Knowledge of the fundamental properties of skeletal muscle is still very incomplete, but it is incomparably greater than our knowledge of these properties in other forms of muscle. This is particularly regrettable because in the treatment of disease a knowledge of the properties of cardiac and plain muscle is of far greater importance than a knowledge of the properties of skeletal muscle. It can only be hoped that the investigators who have obtained such brilliant results with skeletal muscle will seek new fields to conquer and will lighten our darkness in these other fields.

The volume under review is of more interest to the physiologist than to the clinician, but past experience assures us that every advance in the knowledge of the fundamental properties of living matter sooner or later produces results capable of direct clinical application, very often in quite unexpected directions. It is impossible to prophesy the results of research, but it appears probable that as soon as the properties of cardiac and plain muscle are analysed with the same care as has been applied to skeletal muscle, results of the greatest importance to clinical medicine will be forthcoming.

#### THE CONTINUITY OF LIFE.

IN his foreword to *The Physiology of the Continuity of Human Life*,<sup>4</sup> which is based on lectures given at the University of Glasgow during the last five years, Professor D. NOËL PATON protests against *ex cathedra* teaching as soul-destroying, alike for the teacher and the taught,

<sup>4</sup> *The Physiology of the Continuity of Human Life*. By D. Noël Paton, M.D., B.Sc., LL.D., F.R.S., Regius Professor of Physiology, University of Glasgow. London: Macmillan and Co., Ltd. 1926. (Demy 8vo, pp. x + 226; 79 figures. 12s. net.)

and instances as examples on which a decision may have been prematurely made the Mendelian laws of inheritance, the part played by chromatin in inheritance and in the determination of sex, and the impossibility of the transmission of acquired characters. The broad-minded, though to some it may seem iconoclastic, atmosphere of these lectures may be illustrated by his treatment of the last much discussed question; the evidence is summed up to the effect that while a large number of acquired modifications cannot be transmitted, there is evidence that in certain somal changes the germ cells are affected, and that this modification is transmitted. Thus a number of examples are quoted to support the opinion that in parthenogenesis environmental conditions may play a part in the determination of sex; in a special chapter on the influence of the soma on the gonads, it is said that the interstitial cells of the gonads, the adrenal cortex, the thymus, thyrocytes (the Galenic spelling of which is deliberately adopted), all seem to exert an influence on the germ as well as on the somal cells; again, the interstitial cells of the gonads and the cells of the adrenal cortex are held to be ancillary to, and have a similar origin to, the germ cells, and may indeed be considered as germ cells; and that hence these two should not be regarded as proving the influence of true somal cells on the germ cells. The eugenists who follow Weismann regard education or cultivation of characters in the individual as futile for the race, whereas those who accept Professor Noël Paton's examples of the influences of acquired modifications on the gametes can believe in the beneficial effects of education, in the broadest sense of the term, on future generations. As regards the correlation between chromosome distribution and sex determination, the conclusion reached is that it is not causal, the chromosome arrangement being perhaps merely the morphological expression of a particular line of metabolism, and the determination of sex depending upon the nutritional state of the soma or other external factor.

The influence of the gonads on the soma is successfully illustrated by figures of the interstitial cells, and attention is drawn to Boring and Morgan's description of two forms in the Sebright bantam cock, one small, the other large and resembling the luteal cells, thus suggesting that in every individual there may be two kinds of sex-determining cells, one predominating over the other. Steinach's various experiments receive due attention, and Professor Noël Paton considers that while the sex of the germ is determined by the metabolic activities of the parental gametes—whether the result of hereditary inertia or of the influence of extrinsic factors—the development of the secondary sex characters of the soma depends on the germ cells or on their ancillary cells.

In conclusion we may say that these pleasantly written lectures contain not only much information but much stimulating food for thought.

#### MALARIA.

THE volume on *Malaria*,<sup>5</sup> by Professor MARCHOUX of the Pasteur Institute, is the fifth of the treatise on medicine and therapeutics, edited by Professors Gilbert and Carnot; it is an admirable textbook of the subject, bringing together in one handy volume practically all the facts known at the present time; it will consequently be a welcome addition to the library of malariologists. It is divided into four main parts. The first, parasitological, gives an account of the different parasites, their discovery and life-history, and of the anopheline hosts, and discusses the question of the unity or multiplicity of the parasites, a subject on which the author read a paper at the First International Malarial Congress held at Rome last October. The parasite of subtertian malaria is denominated *Plasmodium praecox* in this first part, but *P. falciparum* thereafter, while the parasite of avian malaria (to which the name *praecox* is usually assigned) is called *P. relictum*.

The second part, which is devoted to the pathology of the disease, includes the clinical aspect, the pathological anatomy, diagnosis, and prognosis. It contains a most

<sup>5</sup> *Nouveau Traité de Médecine et de Thérapeutique*. V. Paludisme. Par Marchoux, Professeur à l'Institut Pasteur. Paris: J. B. Baillière et Fils. 1926. (Roy. 8vo, pp. 366; 138 figures.)

useful table, the like of which we do not remember seeing in any previous work, giving the points by which the variety of parasite and the stage of its development can be determined from examination of blood smears. The third part is concerned with treatment, and is adequate, while the fourth and last takes up the question of prophylaxis in its general and special aspects, discussing the different measures suitable to different circumstances deduced from information gained in various parts of the globe where the matter has been scientifically undertaken.

The illustrations are not in all cases up to the high standard of the text; misprints are very few, but we note that Sir Arthur Shipley, who, with Professor Nuttall, is mentioned fairly frequently, has the misfortune of having his name wrongly spelt throughout the book, and the name Wellcome contains one mistake in each syllable. These are errors which could easily have been avoided.

There is one subject the omission of which is somewhat surprising in a book so up to date in other respects—namely, the use of the parasite in the treatment of general paralysis. The only reference to this that we have seen is a brief line in which it is stated that "malaria is credited with having a retrogressive effect on the symptoms of general paralysis." The work, however, is a mine of information, imparted with the lucidity and charm which characterize all that comes from the pen of its author.

#### DIAGNOSIS AND TREATMENT IN HEART AFFECTIONS.

WHEN SIR JAMES MACKENZIE prepared the lectures ten years ago which form the basis of the *Principles of Diagnosis and Treatment in Heart Affections*\* he had in view two main objects. One was to place the essentials of heart failure within the grasp of the general practitioner; the other was to stimulate research along lines previously neglected. With the former of these objects still in view the editing of the second edition was placed in the hands of his colleague, Dr. JAMES ORR, at the St. Andrews Institute, and for any alterations in the present edition he is also responsible. He has aimed at making only such changes as would bring it into line with the newer views enunciated by Mackenzie in his later years. The arrangement of the matter has also undergone some slight modification, and the book is divided into four parts, dealing with heart failure, affections of the regulating mechanism, other affections of the heart, and prognosis and treatment.

Insistence on making facts fit a hypothesis is always a risky undertaking, and we feel that in some cases the principles of logic are strained in the attempt. This is perhaps most noticeable in the paragraphs dealing with the nature of auricular fibrillation and auricular flutter. Apart from points such as these, which are quite subsidiary as far as the general practitioner is concerned, the book will continue to fill a valuable place in dealing with cases of heart disease.

#### NOTES ON BOOKS.

*Experimental Pharmacology as a Basis for Therapeutics*† is an English translation of the seventh edition of the well known textbook by Professor HANS H. MEYER and the late Professor R. GOTTLIEB. The first German edition was published in 1910, and a translation into English appeared in 1914. The present volume, by Professor V. E. HENDERSON of Toronto, is thus the second English translation. The textbook itself has passed through seven editions in fifteen years. Professor Gottlieb died before the appearance of the last edition, but Professor Hans Meyer, the doyen of European pharmacologists, has continued the work alone, and the book still bears the stamp of his wide knowledge and philosophic insight. As the title indicates, it aims at presenting pharmacology as an introduction to therapeutics; the subject, therefore, is arranged with reference to the actions which it is desired to produce, and the chapters bear such headings as pharmacology of digestion, circulation, respiration, etc. A clear exposition is given of the scientific

basis for the art of therapeutics, and will attract all who are interested in the general principles underlying the choice or use of drugs. The translation has been carefully made, and certain minor alterations in arrangement and nomenclature have been made which render it more easily intelligible. As it is twelve years since the earlier English translation appeared, the new volume will be practically a new book to English readers.

The first edition of Dr. H. E. STEWART's *Diathermy, and its Application to Pneumonia*, which was favourably reviewed in our columns (1925, vol. ii, p. 849), has been exhausted, and the second edition, with the modified title *Diathermy with Special Reference to Pneumonia*,\* which is in accord with the broader contents of both editions, shows the continued success of this method of treating lobar pneumonia by the expanded experience of 248 cases, as compared with 67 in the former edition. The author's claims are that the treatment is harmless provided the technique is properly carried out, and that it relieves the symptoms and reduces the mortality, though it does not prevent relapses nor shorten the period of illness. In 96 per cent. of the cases thus treated, however, the temperature at once began to fall by lysis. Stress is laid on the importance of starting the treatment as early as possible, and the author states that, as far as he knows, in cases in which the treatment was started before the third day death has occurred in two only. The method is said to be valuable also in bronchopneumonia and in influenzal, post-etherization, and hypostatic lung lesions, though the results are not so striking as in lobar pneumonia. The question whether or not diathermy of the unaffected lobes in lobar pneumonia will prevent extension of the consolidation and relapses is raised, but has not yet been investigated. It is confidently asserted that diathermy through the heart improves the coronary circulation and minimizes the effect of toxins on the myocardium.

We have recently received the fifth and final instalment of the lexicon of nutrition† by Professors E. MAYERHOFER and CLEMENS FIRQUET; the last two parts of it were noticed a few months ago (April 3rd, 1926, p. 622). Among the subjects discussed are Count Rumford, author of "An essay on food," edible snails, Schroth's cure, regulation of the diet of the healthy child, the feeding of pigs, asparagus, subcutaneous nutrition, soup, tobacco, dried milk, nourishment in prehistoric times, vegetarianism, vitamins, game, and sugar. The editors are to be congratulated on the completion of this lexicon, which, as we surmised in our notice of the first instalment (February 9th, 1924, p. 242), has fulfilled the promise of being a truly monumental work.

Believing that a book on the *Non-Surgical Treatment of Diseases of the Mouth, Throat, Nose, Ear and Eye* would be of material assistance to the young specialist and the general practitioner, Dr. ODENEAL has produced a volume‡ with that title. He does not keep strictly within the limits he has imposed upon himself in the title, and frequently breaks out into descriptions of treatment essentially surgical. He has, for example, something to say about operations on the nasal septum, much about operations for glaucoma and cataract, and about the extraction of intraocular foreign bodies. It is indeed doubtful, when dealing with special regions, if there is much to be gained by attempting to define any particular method of treatment as surgical or otherwise. In this manner two-thirds of the book is occupied. The second part is entitled "Desiderata," and describes in several chapters vaccines and serums, the vegetative nervous system, the endocrine glands, reactions, signs and symptoms, focal infections, hypersensitiveness, headaches and neuralgias, the cerebro-spinal fluid and blood, x-ray diagnosis, and encephalitis lethargica. The author deals with these matters and some few more in relation to the special regions indicated. All through he refers freely to his own experiences and the opinions he has formed, so that the stamp of his own individuality raises the book above the level of a mere compilation. He has, moreover, by approaching his subject from an unusual standpoint, presented in a systematic manner a somewhat diverse collection of useful information. There are only four illustrations, which are figures of instruments designed by the author.

It is because Dr. GRABHAM's temperament is as genial as the climate of his island home that he has been able to make readable what is in essence little more than a catalogue of

\* *Diathermy, with Special Reference to Pneumonia*. By Harry Eaton Stewart, M.D. Second edition, revised. New York: Paul B. Hoeber, Inc. 1926. (Cr. 8vo, pp. xx + 222; 45 figures, 15 charts. 3 dollars net.)

† *Lexikon der Ernährungskunde*. Herausgegeben von Dr. E. Mayerhofer und Dr. C. Pirquet. 5 Lieferungen. Wien: Julius Springer. 1926. (Sup. roy. 8vo, pp. 315. R.M. 16.50.)

‡ *Non-Surgical Treatment of Diseases of the Mouth, Throat, Nose, Ear and Eye*. By Thomas H. Odeneal, M.D. London: H. K. Lewis and Co., Ltd. 1926. (Demy 8vo, pp. xi + 428; four illustrations. 17s. net.)

\* *Principles of Diagnosis and Treatment in Heart Affections*. By Sir James Mackenzie, M.D., F.R.S., etc., and James Orr, M.B., Ch.B. Third edition. Oxford Medical Publications. London: Humphry Milford, Oxford University Press. 1926. (Demy 8vo, pp. viii + 242; 37 figures. 10s. 6d. net.)

† *Experimental Pharmacology as a Basis for Therapeutics*. By Dr. Hans H. Meyer and Dr. R. Gottlieb. Second edition in English translated by Velyden E. Henderson from the seventh revised German edition. London: J. B. Lippincott Company. 1926. (Med. 8vo, pp. xi + 656; 87 figures. 30s. net.)

plants, shrubs, and trees. It is a volume less for the conscientious reader than for the judicious skipper; and it will move almost to tears those gardeners amongst us who just now are looking out every morning expecting to see dahlias and geraniums cut down by frost, for there is no winter in Madeira. Dr. Grabham's book, which is called *The Garden Interests of Madeira*,<sup>11</sup> is illustrated by several pictures, including a portrait of the author, who was born in 1840.

The third edition of *Gould and Pyle's Pocket Cyclopaedia of Medicine and Surgery*<sup>12</sup> has been revised and brought up to date by Dr. R. J. E. Scott of New York. It is a handy little volume in which the information given is arranged alphabetically, so that reference is easy. Naturally much of what it contains is matter of common knowledge; but in cases of doubt as to the meaning of a term, or the latest treatment of a disease, information in a concise form may be rapidly gained. It is curious, however, that while "hoarhound" and "holocaine" occur in the cyclopaedia, insulin fails to get individual mention and must be searched for under diabetes. The number of cross-references in the book has been largely increased.

<sup>11</sup> *The Garden Interests of Madeira*. By Michael Comport Grabham, M.D., LL.D. London: William Clowes and Sons, Ltd. 1926. (Cr. 8vo, pp. xi + 103; illustrated. 5s. net.)

<sup>12</sup> *Gould and Pyle's Pocket Cyclopaedia of Medicine and Surgery*. Third edition, revised, enlarged, and edited by R. J. E. Scott, M.A., B.C.L., M.D. New York. London: H. K. Lewis and Co., Ltd. 1926. (Fcap. 8vo, pp. 922; illustrated. 12s. net.)

## PREPARATIONS AND APPLIANCES.

### *A Suspension Apparatus for Crowe's Mouth Gag.*

Dr. W. S. THACKER-NEVILLE (Darlington) has designed a suspension apparatus for the mouth gag in tonsillectomy. He writes:

The mouth gag employed in tonsillectomy by Professor Crowe in the Johns Hopkins Hospital, like the Davis mouth gag in this country, requires an assistant or a support. In order to save an assistant this tiring task, and in order to avoid the pressure on the chest caused by another apparatus employed for the same purpose, I have had made the simple apparatus illustrated here. Formerly I used a table to support the hook, but this apparatus is more easily carried about for operations in different places. The

apparatus is made by the Medical Supply Association, Gray's Inn Road, London, W.C.1.

### *A Radium-Needle Stand.*

Drs. Arthur B. Smith and Sydney M. Smith (London, W.) write: This stand, which is 8½ inches long, 4 inches broad, and 2½ inches high, is designed to facilitate the use of radium by the surgeon in operations of access and insertion. The illustration shows the stand with radium needles and tubes in position, together with their attached threads and identification beads. Sterilization may be effected by boiling the stand with the needles and tubes *in situ*, or the needles and tubes may be sterilized separately in spirit and then placed in position. If the former method is

employed the threads are anchored by means of a metal band with an aseptic hinge, which secures them against the end of the apparatus, while the radium tubes remain safely in test tubes passed through the wire loops provided on the lower horizontal support of the frame. At operation the band is swung back to liberate the threads, and the stand is placed on a table close to the operator ready for use. The stand has been made for us by Messrs. J. Gardner and Son, 35, Forrest Road, Edinburgh.

## MEDICAL DEFENCE UNION.

### ANNUAL GENERAL MEETING.

The annual general meeting of the Medical Defence Union was held on September 23rd, with Sir HERBERT WATERHOUSE, the president, in the chair. A total membership of 13,480, a net gain of just over one thousand on the year, was reported by the council.

The annual report laid stress on the additional benefits which the Union has lately provided by assuming responsibility; at the council's discretion, in claims made against a member in respect of the act or omission of a locum tenent not himself a member of a defence society. The employment of an assistant, whose engagement is of a more or less permanent character, is on a rather different footing, and a reciprocal arrangement has been arrived at between the two English defence societies whereby, if the principal is a member of one of them, and his assistant a member of the other, either society will defend its member in an action against the principal arising out of the acts or omissions of the assistant. This arrangement has been extended to the protection of a member of the honorary staff of a hospital in the event of proceedings against him in consequence of the act or failure of a subordinate medical officer who is himself a member of one of the societies.

The report records many instances of assistance given in resisting unjust claims or allegations. In eight cases legal assistance was afforded to members in appeals against decisions of Insurance Committees, with wholly successful results in six, and a reduction of the suggested penalty in the other two. The Union also successfully defended four members summoned to appear before the General Medical Council, and was successful in one of two cases in which it appeared as or in support of the complainant. It has also been in correspondence with the Registrar of the Council with regard to the appearance in a newspaper of signed articles on public health questions by a whole-time medical officer of health. The Union, believing it to be in the interest of the public that such officers should not be debarred from publishing signed articles on public health questions, elicited from the General Medical Council, which had sent a warning letter in one such case, that what it disapproved was only the abuse of this practice, and that each case would be dealt with according to the special circumstances.

An interesting report by the solicitors to the Union (Messrs. Hempton) was also laid before the members. With regard to appeals to the Ministry of Health from the decisions of Insurance Committees, the solicitors state that in their experience such appeals were heard with the utmost fairness, and a full and impartial inquiry was ensured. But the award of costs was seldom nearly sufficient to defray the expense in which the practitioner was involved, and often even such costs as were awarded were irrecoverable owing to the lack of means of the unsuccessful party. They also lay stress upon the expense in ordinary law cases to which practitioners would be subject were it not for the defence society which, in addition to undertaking the defence, indemnified against the costs of the other side and against damages of an unlimited amount. During the last fifteen years, in sixty-seven of the heaviest cases which the Union has been called upon to undertake, the average cost of each case to the society has been £270. In addition to the personal security afforded by membership, the solicitors point out that it is in the interests of the profession that medical men should be members of a defence society; otherwise they are likely to be frightened into settlements, which will encourage the unscrupulous litigious speculator. The solicitors express regret that in the legal profession there is no body corresponding to the Union, and that to obtain adequate cover it is necessary for the lawyer to take out an insurance policy costing many times the amount of the Union's annual subscription.

Sir HERBERT WATERHOUSE, in commending the report of the meeting, expressed regret that the British Medical Association (having regard to the position of its members who were on the General Medical Council when cases in which the Union was concerned came forward) had been unable to accept the invitation to nominate two members for appointment as vice-presidents of the Union; he added that the Union was fortunate in having already on its council three members of the Council of the British Medical Association. He welcomed the recommendations in the report of the Royal Commission on Lunacy as holding out the prospect of early legislation to afford a larger measure of protection for doctors certifying mental cases. He also paid a high tribute to the services rendered to the Union by its general secretary (Dr. James Neal) and its solicitors.

The report of the council and the financial statement (which showed assets to the amount of £24,000) were adopted unanimously, and Dr. W. T. Lydall, Mr. R. F. Jowers, and Dr. Seymour Taylor, the retiring members of council, were re-elected.

## THE INNOCUITY OF SCARLET FEVER.

## INTERNATIONAL STATISTICS.

In May, 1924, the Office International d'Hygiène Publique, at the suggestion apparently of the British delegate, decided to collect information on the incidence and control of scarlet fever from the various countries represented in the office. Some of the matters disclosed in the replies to the questionnaire were enumerated in the *Bulletin* which reported the session of the Office International in October, 1924. It has now been thought advisable to analyse all the information so far collected; and the analysis has been published by the Office International d'Hygiène Publique (*Bulletin*, tome xviii, 1926, fasc. Nos. 6 and 7).

The first part of the publication consists of a report by Dr. Allan C. Parsons, with an introduction by Sir George Buchanan, who presented it, on the comparative prevalence of scarlet fever, its characters, and the methods adopted for combating it in various parts of the world. This is followed by notes from Drs. Cantacuzène, Amiot, Frey, and Madsen on scarlet fever in Rumania, Canada, Germany, and Denmark respectively. We do not propose to enter into a detailed account of Dr. Parsons's lengthy analysis of the information received from some thirty countries, or to follow necessarily the order in which he deals with his subject; but rather, after some preliminary remarks on the distribution and character of the disease, to indicate the position with regard to infectivity, notification, the value of hospital treatment, disinfection, and quarantine before return of the patient to school.

*Historical.*

However old a disease scarlet fever may be, Dr. Parsons notes that the first definite record of its occurrence dates from the middle of the sixteenth century, and that the confusion that existed between scarlet fever, measles, erysipelas, and probably diphtheria, was not cleared up until the time of Sydenham (1676). After 1740 the disease assumed a graver form, and towards the end of the eighteenth century there was an unmistakable increase in its malignancy. After the beginning of the nineteenth century there was a general lull, until the wave of malignancy again rose in the British Isles in 1831, and the disease contributed seriously to the death rate among children. About 1875, however, there was a sudden and remarkable drop in mortality and fatality rates; this drop has continued progressively, and recently complications have become less frequent. The attack rate, though less, has not shown a parallel declension; with a curious very large drop during the war, it has since gone up again. Dr. Parsons observes that the drop in mortality and fatality rates occurred before the introduction of compulsory notification and before the common use of hospitals for infectious diseases. It may, however, be suggested that both these provisions for the control of infection were based largely on recollections of the malignancy of scarlet fever before 1875, and on a fear of this disease which those who were students in the eighties and nineties can well remember.

Throughout all the epidemics from the sixteenth to the nineteenth century the chief incidence of scarlet fever was in North-West Europe and North America. It did not appear in South America until 1830, nor in Australia until about 1850. Little has been heard of its presence in tropical or semi-tropical countries; but in more recent times it has become a matter of some concern in south-eastern Europe.

*Infectivity.*

Down to the end of the last century scarlet fever was still regarded as a highly infectious and dangerous disease. The case mortality, it was said, might rise to 30 or 40 per cent. Though it was most common in children, it occurred, or was believed to occur, in a particularly malignant form in puerperal women. The source of infection, apart from contact with the patient, was supposed to exist chiefly in the peeling of the skin, so that fomites and even letters from scarlet fever patients could communicate the disease.

It was a common cause of nephritis, and sometimes of endocarditis. Patients were not allowed to mix with other people until desquamation was complete; and one of the great difficulties in the return to normal existence was the length of time before the soles of the feet ceased to desquamate. In any event the period of isolation could not be less than six weeks. This was the recognized routine in England, though in neighbouring countries ideas were often not so strict. During the illness bedside disinfection was practised, wet sheets were hung over the door, and overalls were worn by the attendants. After an attack the patient, his nurses, his room and its contents had to be disinfected as a final step. The disinfection was undertaken by the public authorities, who ruined much material in the process. It was because of its seriousness and danger that scarlet fever was among the diseases made compulsorily notifiable in 1899. It was largely to accommodate cases of scarlet fever that the hospitals of the Metropolitan Asylums Board and other public bodies were built.

*Recent Behaviour of the Disease.*

The information at the disposal of Dr. Parsons is to the effect that scarlet fever is a notifiable disease in the great majority of countries where it is known to exist. His information, however, is not complete, probably because in countries where the disease is practically unknown it has been found difficult to answer the questionnaire. Comparison of the statistics of different countries is also difficult, because census figures are not always accurate and the methods of notification and death registration are not uniform. But from the information collected by the Office International d'Hygiène Publique it has been possible to review the description we have given of scarlet fever in England at the end of the last century in the light of knowledge of its behaviour to-day. In the first place, scarlet fever is no longer the dangerous disease it used to be. It is true that in Bulgaria, in 1924, a mortality of 2.66 per 10,000 population was recorded; among the Serbs, Croats, and Slovenes a mortality of 1.68, in Rumania 1.01, and in Danzig 1.15. But the English rate has sunk from 10 or 12 in the sixties to 0.22 in 1924. A similar fall has occurred in all the countries in Western Europe, so that since 1900 very few of these countries have shown a mortality rate over 1 per 10,000 of population.

Fatality rates are more difficult to compare, because the completeness of notification varies in different countries. The Bulgarian delegate, Dr. Golosmanoff, admitted that this might be true of his country. In London, where the majority of patients (over 90 per cent.) are treated in the hospitals of the Metropolitan Asylums Board, the fatality figures are much more exact. Consequently, whatever may be said of a rate of 14 per cent. in Italy, 17 in Bulgaria, 22 in Jugo-Slavia, or 13 in Poland, there can be little doubt about the 1 per cent. in England and Wales. In Scotland this rate is doubled; but this may be due to less thorough notification of the disease. This English rate of 1 per cent. compares with one of 12.6 per cent. in the quinquennium 1877 to 1881.

The morbidity rate in England and Wales has not shown any marked decline, except during the war, when the decline in this country, as well as many others, may perhaps be explained by the fact that the machinery for control was considerably disorganized. In 1911 the rate per 1,000 of population was 2.9; in 1925 it was 2.35. These figures, as Dr. Parsons says, "show no substantial submission of the disease to the highly organized measures of control used against it. . . . They compare unfavourably with those of some countries where the measures of control are seemingly less comprehensive." In noting a similar failure of the morbidity rate to keep pace with the decline in the mortality rate in Switzerland, Dr. Carrière suggests that too much attention is perhaps paid to scarlet fever and diphtheria, and that measles is a more important disease than either. In Australia there has been "increased incidence" of scarlet fever "without increased mortality of late years." Yet there is no sign, notwithstanding this unsatisfactory morbidity rate, of any tendency to reversion to a severe type in England and Wales,

though there is evidence that in some countries, especially in South-East Europe, scarlet fever remains a severe disease.

#### *Spread of the Disease.*

The majority of the reporters are of opinion that the spread of scarlet fever is almost entirely a matter of personal contact, often contact with slight abortive cases. Much importance is attached to the mild or "missed" case. Opinion differs greatly on the subject of "carriers"; and Dr. Scholes of Melbourne, who lays particular stress on "missed" cases as a source of infection, and on patients with post-nasal or pharyngeal catarrh, or otorrhoea following an attack, submits that there is no evidence of the existence of "healthy carriers," which he regards as merely "a pleasant and easy hypothesis." Dr. Scholes and the Norwegian reporter regard the influence of schools in spreading the infection as very slight; but in Bulgaria it is thought that schools play an important role. Milk is still an occasional, though rare, medium of infection in England; but Dr. Grain of Norway says that no great explosions of epidemicity, as in milk- or water-borne typhoid outbreaks, occur.

#### *Isolation.*

The extent of hospital provision for the treatment of scarlet fever varies greatly in different countries. In England and several other countries the majority of patients are so treated, and apparently parents prefer that it should be so. In Italy two-thirds of the patients are treated at home. In Bulgaria hospital isolation is not considered essential. In Greece lack of transport facilities makes it almost impossible. In countries where scarlet fever has not caused much concern it may be assumed that no special hospital arrangements are necessary. It is interesting to remember that during the war, when there was shortage of hospital accommodation, the Ministry of Health asked medical practitioners to send only severe cases into the Metropolitan Asylums Board hospitals; it is interesting also to note that in Holland, during epidemic times, only grave cases are admitted to hospital. In Norway slight cases, both in towns and villages, are now treated at home.

#### *Disinfection.*

Disinfection in scarlet fever may be considered under two headings. In the first place, there is "bedside" disinfection, the object in view being the destruction of germs as they are produced by the patient. This system is based on the view that only the patient and his recently soiled clothes, food vessels, etc., are infectious. In some countries the opinion is gaining ground that this is the only form of disinfection which need be carried out. The efficacy of "terminal" disinfection is gradually coming to be held in doubt. Thus in Norway fumigation is not officially recommended, but is carried out if desired; and although bedclothes and underclothing are boiled, and steaming is carried on in most cities, Dr. Karlstroen remarks that "if the disease steadily declines in malignancy, and if ear and secondary complications cease altogether, we must weigh earnestly the possibility of dispensing with isolation and disinfection." In the United States particular attention is given to mechanical cleansing and laundering, boiling and burning. Surface disinfection of the sick-room with formaldehyde is regarded as relatively unimportant and, indeed, unnecessary. In Denmark disinfection is gradually being given up in many places, especially when the patient has been removed to hospital. In Holland opinions differ: in some cities it is only carried out by request and in order not to shake the public belief in the infectiousness of scarlet fever.

The quarantine period for patients in the United States is from four to six weeks, but differs in different States. Four weeks is the minimum period in Australia and Italy; five weeks in Holland, and six weeks in Stockholm. In several countries desquamation is still taken as a guide to freedom from infection; but in Norway peeling of the feet is disregarded. In Sweden any peeling is disregarded after

six weeks. In Holland there is an opinion that late peeling is innocuous. In Melbourne patients are only passed for discharge when they are free from haemolytic streptococci in the nose and throat, and from any streptococci which prove very fatal to guinea-pigs. The date of return to school varies in different countries from seven to twenty-one days after discharge from hospital or "after all danger is considered to be over." Dr. Parsons's report embodies a long review of the "Dick" test, concluding with the opinion of Dr. King in America that, while many American physicians consider that the antitoxic serum should always be used in severe cases for curative purposes, the time has not yet arrived to report definitely about the value of the toxin for diagnostic and prophylactic purposes.

#### *Conclusions.*

The report of Dr. Parsons and the other matter contained in the *Bulletin* of the Office International d'Hygiène Publique are of great interest, and serve to show the value of Governmental inquiry in some forms of research. For it is doubtful whether any private scientist could have succeeded in obtaining from thirty countries such answers as the Office has received to its questionnaire. At the same time, whatever may be the theoretical value of the accumulation of such data, the Governments concerned ought to bear in mind the more practical point—whether the information gained can be used to lighten the burdens imposed on their subjects and to economize their countries' resources. Such, we gather, was to some extent the object of the Ministry of Health when its representative, Sir George Buchanan, proposed the inquiry. Dr. Parsons, in the course of his report, states that the chief reason for the inquiry by the Ministry of Health into the present position of scarlet fever in England and Wales was the fact that the morbidity rate shows little sign of decline, although in many great cities the proportion of children of susceptible age is getting less and less. Sir George Buchanan, on the other hand, in his introduction to the report, states that in Great Britain it is felt necessary to revise the traditional system of hospital isolation in the treatment of scarlet fever, in order to set free beds for other diseases, such as measles. For this reason he regards the evidence from other countries as to isolation as being of the greatest value.

The facts seem to be as follows. Before 1875 scarlet fever was a grave disease, with a heavy mortality among children and a tendency to permanent sequelae among the survivors. Partly owing to the mental impression made by the former gravity of scarlet fever an elaborate and costly system of control was developed. This system involved the country in the cost of notification, of health inspectors, of disinfection, and of hospitals mainly for scarlet fever cases; but the evidence that these measures have controlled the disease is inconclusive. The gravity of scarlet fever had already begun to decrease, though the number of cases remained, and still remains, at much the same proportion to the population. Experience during the war showed that not much harm was done by leaving milder cases to be treated in their own homes. Finally, the experience of various countries throws doubt on the value of many of the original ideas for controlling the disease, brings in question the necessity of disinfecting the patient's room and the importance of desquamation, and casts doubt on the doctrine that infection could be spread by packing up portions of the patient's scales in his letters.

Unfortunately it does not seem to have been a part of the functions of the Office International d'Hygiène Publique to formulate any conclusions from the facts and opinions which it has collected. We look forward, however, to hearing more on the matter from the Ministry of Health. We may remind our readers that there are at present about thirty diseases on the notifiable list. The report before us is evidence of the value of the inclusion of scarlet fever in the original list of nine notifiable diseases. We hardly like to suggest that possibly that inclusion has served its turn; but the report does suggest that perhaps an occasional overhaul of the list of notifiable diseases might lead to some revision.

## Nova et Vetera.

## BILLS OF MORTALITY.

For three hundred years the only official statistics of life and death in the metropolis were to be found in the Bills of Mortality of the City of London. The Plague was probably the cause of their institution. There had been severe epidemics of this disease in the years 1513, 1516, and 1518, and in 1528 there were not wanting signs of its return, which induced King Henry VIII and his advisers to require of the Lord Mayor from time to time a statement of the weekly mortality in and around the city.

Dr. Creighton, in his *History of Epidemics in Britain*, states that "on the 20th" (October, 1532) "Audely the Lord Chancellor writes that many die of the plague, the sergeants in Fleet Street have left in consequence, the Inner Temple has broken commons, the lawyers being in great fear. The Council have commanded the mayor to certify how many have died of the plague. That is the first known reference to the London Bills of Mortality." But Dr. Creighton has brought to notice from the Record Office a return made by the Lord Mayor in 1528. This consists of a bald list of burials, parish by parish, under two headings, one being "of the plague" and the other "not of the plague." It is probable that at first these Bills were only returned in years of epidemic disease, but a hundred years later they had become established as weekly and annual records. Parish registers of births, marriages, and deaths were instituted throughout England in 1539, but at first they were very irregularly kept, although there were and are remarkable exceptions.

From the bald statement of plague and not-plague deaths in 1528 the weekly and annual Bills of Mortality had grown into rather elaborate documents a hundred years later and were rendered in a form which was kept up until a more accurate method of recording vital statistics was introduced less than a century ago. In the *London Medical Gazette* for February 20th, 1836, there appeared the "Weekly account of Burials," dated February 16th. The last of the Annual Bills appears in this volume of the *Gazette*, for the Act of Parliament enacting the registration of births and deaths was passed in 1836, and the Registrar-General's functions began in 1837. So well established had the term "Bills of Mortality" become that it was used as a topographical term signifying London and suburbs. Thus Thackeray in the *Newcomes* (1854) wrote of Barnes Newcome: "In a word, he was as scrupulously whitened as any sepulchre in the whole bills of mortality."

There is no complete series extant of the early Bills of Mortality, but a good many specimens are preserved in the Guildhall Library, and facsimiles were printed by the father of vital statistics, John Graunt, F.R.S., Captain of Trainbands and Haberdasher, in his book "Natural and Political Observations mentioned in a following Index, and made upon the Bills of Mortality, etc., etc.," of which the *Epistle Dedicatory* is dated 1662, although it was not published until 1665. His account of the way in which the statistics were made and collected is worth quoting:

"We have hitherto described the several steps whereby the bills of mortality are come up to their present state: we come next to show how they are made and composed, which is in this manner, viz., when anyone dies, then either by tolling or ringing of a bell, or by bespeaking of a grave of the sexion, the same is known to the searchers, corresponding with the said sexion. The searchers hereupon (who are ancient matrons, sworn to their office) repair to the place where the dead corps lies, and by view of the same, and by other enquiries, they examine by what disease or casualty the corps died.

"Hereupon they make their report to the Parish Clerk and he, every Tuesday night, carries in an account of all the burials and christenings happening that week to the clerk of the hall. On Wednesday the general account is made up and printed, and on Thursday published and dispersed to the several families who will pay four shillings per annum for them."

Speaking of venereal disease, he says:

"In the next place, it shall be examined under what name or casualty such as die of these diseases are brought in: I say, under the consumption; for as much as all dying thereof die so emaciated and lean (their ulcers disappearing upon death) that the old women searchers, after the mist of a cup of ale, and the bribe of a two groat fee, instead of one, given them, cannot tell whether this

emaciation or leanness were from a phthisis, or from an hectic fever, atrophy, etc., or from an infection of the spermatie parts, etc."

It is evident that statistics thus compiled were hardly likely to be accurate, even if they were honest, of which there must be a grave doubt, for the searchers, who were only allowed a fee of one groat (fourpence) per corpse, must often have been tempted, as Graunt says, to conceal the real cause of death when it was known; while their ignorance and the fact that they did not see the patients alive prevented their making a satisfactory diagnosis. No doubt many deaths from epidemic and contagious disease were concealed by such means.

From December, 1624, to December, 1625, the Bills dealt with 97 parishes within the walls, 16 parishes without the walls, standing part in the liberties and part without in Middlesex and Surrey; and at the Pest House and 9 out parishes (including St. Giles-in-the-Fields, Whitechapel, St. Martin's-in-the-Fields, etc.). In the year 1625 the city of Westminster was added, and in the year 1660, just before Graunt's book appeared, Islington, Lambeth, Stepney, Newington, Hackney, and Redriff (that is, Rotherhithe) were included in the Bills. Graunt refers to the crowded state of the city, and his complaint about the traffic has a very modern ring.

"But now both these Gates" (Newgate and Ludgate), he wrote, "are not sufficient for the communication between the Walled City, and its enlarged Western Suburbs, as daily appears by the intolerable stops and embarras of Coaches near both these gates, especially Lud-gate."

The complete Bill for the year 1629 is headed as follows: "A General Bill for the present yeere, ending the 17th of December, 1629, according to the report made to the King's most excellent Ma<sup>ty</sup> by the Company of Parish Clerks of London," etc. The total burials were 8,771, being 4,663 males and 4,103 females. "Whereof of the Plague 0." This was not a plague year.

The causes of death were set forth under sixty headings as follows:

## The Diseases and Casualties.

|                         |       |                          |     |

| Jaundis                 | 47    |                          |     |

## Buried:

|         |       |
|---------|-------|
| Males   | 4,663 |
| Females | 4,103 |
| In all  | 8,771 |

Whereof of the Plague 0.

This list of diseases hardly corresponds with the *Nomenclature of Diseases* of the Royal College of Physicians, and some of the headings may require explanation. For instance, "Meagrome," which is bracketed with "Appoplexy," is, no doubt a form of megrim, a corruption of migraine. "The Meagrimis" was loosely used for various affections of the nervous system. "Blast" is defined by Halliwell (*A Dictionary of Archaic and Provincial Words*, tenth edition, 1887) as an inflammation or wound, an ailment attributed to the action of witchcraft (Somerset); also, to

cast the eyes up in astonishment (Devon); and planet-struck, paralytic (Linc.); "a blasting, or planetstreaking" (Florio). The same authority thus explains "Chrissome": "Chrissoms in the Bills of Mortality are such children as die within the month of birth, because during that time they are to wear the chrissom-cloth," which is "the white cloth which is set by the minister of baptism upon the head of the child newly anointed with chrism after his baptism." Burst is inexplicable. Wolfe is of course the English of lupus. The meaning of "Frets" is obscure.

"Jawfalne" or Jawfallen is not to be found in any of the dictionaries consulted, but Dr. John E. Morgan<sup>2</sup> of Manchester, writing in 1862, quoted Dr. Morrison, who practised for eight years in Demerara, as stating that trismus nascentium was there called "jawfall." This name seems at first sight to be chosen on the principle of *lucus a non lucendo*, but some writers describe an obvious relaxation and dropping of the jaw as characteristic of the last stage of trismus.

"Livergrowne," which Captain Graunt connected with rickets, means enlargement of the liver. "Mother" is of course hysteria. "Tissicke" is phthisis. In the Bills for some other years we find as causes of death Headmouldshot, Horseshoehead, Mouldfallen, and Flocks-and-smallpox. The first is explained in the *Lexicon Physico-Medicum* of Dr. John Quincy (tenth edition, 1787) thus: "This is when the sutures of the skull, generally the coronal, ride; that is, have their edges shot over one another; which is frequent in infants, and occasions convulsions and death." A similar pathological theory seems to have survived for many years, for Dr. Marion Sims<sup>3</sup> in 1846 and 1848 attributed trismus nascentium to displacement of the occipital bone, and in 1884 Dr. Hartigan<sup>4</sup> of Washington, D.C., strongly supported him, quoting many authorities and cases.

Quincy gives "Horseshoehead" as "a disease in infants, in which the sutures of the skull are too open, the opposite to Headmouldshot." According to Nares's *Glossary* of 1859 "Flocks" means sediment. The relation of this word to small-pox is obscure.

"Mouldfallen" seems to mean depression of the fontanelles. "Rising of the Lights" is still used in some places for emphysema, but it is difficult to say why cases of this condition should in some Bills be bracketed with "Mother." The two together were credited with 84 burials in 1634, in which year rickets first appears as a cause of death (14 cases). "Overlaid and starved at Nurse" and "Greene sickness" need no explanation. "Greefe" and "Frighted" are less obvious as causes of death. There were 43 burials of drowned persons in 1629, and in 1653 fifteen persons hanged themselves. What shares religion, politics, and poverty had in causing these suicides the Bills say not.

It is evident that these records are in general very untrustworthy as indications of the diseases which caused death, but one startling inference can be drawn from them—namely, the enormous infantile mortality in London in those days. We may safely conclude that the following headings can only refer to children: Abortive, Convulsions, Starved at Nurse, Teeth, Chrissomes and Infants, and Sore Mouth and Thrush. By adding these together for the year 1629, the total of 3,600 infantile deaths is obtained, out of a total at all ages of 8,771. Probably even this is too low, for there were 449 deaths from "Bloody flux, scowring and flux," of which some surely should belong properly to the category of infantile diarrhoea. Moreover, there are no deaths from respiratory diseases among the 3,600.

Pepys has several references to Grant or Graunt in his *Diary*. He notes that on March 24th, 1662, while his wife was shopping, he went "To Westminster Hall, and there bought Mr. Grant's book of Observations upon the weekly bills of mortality, which appears to me, upon first sight, to be very pretty." On July 25th, 1665: "This day my Lord Brunker did give me Mr. Grant's book upon the Bills of Mortality, new printed and enlarged." Pepys was not consistent in the spelling of names, but the accepted form is Brouncker. He was William, second Viscount, "a respectable mathematician," who was made M.D. at Oxford in 1647, and was the first President of the Royal Society, of which Pepys was elected a Fellow on February 15th, 1665.

Graunt had been elected three years before, and Wheatley, in his edition of the *Diary*, recalls in a footnote that he was recommended by the King (Charles II), and quotes from Sprat's history of the Society that "his Majesty gave this particular charge to his Society, that if they found any more such tradesmen, they should be sure to admit them all, without any more ado." Graunt was a haberdasher in Birchin Lane in the City of London, where he was born in 1620 and where he died in 1674. Pepys, on April 20th, 1663, called on Graunt and "there saw his prints, which he showed me, and indeed are the best collection of any things almost that ever I saw, there being the prints of most of the greatest houses, churches, and antiquities in Italy and Franco and brave cuts."

The Company of Parish Clerks, which was for so long responsible for the preparation and printing of the Bills of Mortality, still exists and has its Hall in Silver Street, near Wood Street, in the City. Originally the clerks were singers, whose functions were rather like those of vicars choral in a cathedral. The company was licensed as a guild in the year 1233 as the Fraternity of St. Nicholas. Their latest charter, granted by James I in 1611, directs that only such shall be admitted to be clerks as are "able to sing the psalms of David and to write." Charles I granted the company leave to have and use a printing press for the production of copies of those Bills of Mortality which have been the subject of this paper.

E. M. L.

## ROYAL MEDICAL BENEVOLENT FUND.

At the last meeting of the Committee sixty-four cases were considered and £785 15s. 6d. voted to fifty-one applicants. The following is a summary of some of the cases relieved.

L.R.C.P.Ed., aged 73, who practised until 1924. Since lived with aged mother until her death last year. Has been offered a home with a married daughter, but must contribute towards his maintenance. Only income old age pension. Voted £40 in twelve monthly instalments.

Daughter, aged 64, of M.R.C.S. who died in 1859. Now lives in an almshouse with an allowance of £13 a year; only other income £25. Friends gave £2. Voted £30 in twelve monthly instalments.

Widow, aged 62, of M.R.C.S. who died in 1923. Owing to ill health quite unable to earn her own living and is entirely dependent on her mother, aged 83, whose only income is a small army pension. Voted £30 in twelve monthly instalments.

Widow, aged 59, of M.B.Glas. who died this year. Only income £50 per annum. Son, aged 22, is apprenticed to engineering and has two and a half years to serve; he receives a guinea a week and she has to supplement this to pay his board and lodging. Premises have been secured to enable her to set up a tea-shop, and on the strong recommendation of the Fund's visitor a grant was made of £20 in twelve monthly instalments, also £10 to help furnish the premises.

Widow, aged 58, of M.R.C.S. who died suddenly this year. Dependent on two daughters, bank clerks. Only income £14 per annum. Rent of flat taken on lease £125 per annum. Asks for help for boy, aged 15, who has a scholarship at a public school. Voted £10 in two instalments.

Widow, aged 68, of M.D. who died in 1919. Has a great difficulty in obtaining work on account of a mentally deficient daughter, aged 26, who needs care. They are now dependent on a married son and his wife, but the son is now out of work and his wife's earnings are their only support. Arrangements are in hand to secure a home for the daughter and £26 in twelve monthly instalments was voted to the applicant.

Widow, aged 38, of M.R.C.S.Ed. who died last year. When estate is realized there will be an income of about £45 per annum. Applicant asks help with daughter's school outfit and expenses. Voted £20.

Three children of M.D.Ed. who died in 1916. Only income £15 per annum, and uncles contribute £100 per annum. They live with a grandmother and an aunt. The Fund has helped with the maintenance to the extent of £93 during the last eight years, and voted a further £18.

Daughter, aged 67, of M.R.C.S. who died in 1885. Applicant is one of a family of eleven children and supported herself until 1919, when, owing to the war, her employers closed down. Unable to obtain another post she now lives with a married sister and helps her in the house, but the sister can ill afford to keep her. Relieved three times. Total £54, and now voted £26 in twelve instalments.

M.D.Ed., aged 72, is bedridden and supported by his brothers, but they are unable to do more, and the Fund was approached for a grant for pocket money. In 1925 the Fund voted £17, and now a grant of £18 in twelve instalments has been made.

Subscriptions may be sent to the Honorary Treasurer, Sir Charters Symonds, K.B.E., M.S., at 11, Chandos Street, London, W.1.

The Royal Medical Benevolent Fund Guild still receives many applications for clothing, especially for coats and skirts for ladies and girls holding secretarial posts, and suits for working boys. The Guild appeals for second-hand clothes and household articles. The gifts should be sent to the Secretary of the Guild, 58, Great Marlborough Street, W.1.

## British Medical Journal.

SATURDAY, OCTOBER 9TH, 1926.

### APHASIA AND KINDRED DISORDERS OF SPEECH.

ANOTHER chapter of profound interest and importance has been added to the long history of the study of aphasia by the publication in complete form of the record of Dr. Henry Head's researches. The work is published in two handsome volumes of small quarto containing together about 1,000 pages, under the title of *Aphasia and Kindred Disorders of Speech*.<sup>1</sup> The substance of Dr. Head's views has already been made known in his *Linacre and Hughlings Jackson Lectures* in 1920 (published in *Brain*) and in the issue of *Brain* for November, 1923. In the present volumes his observations and conclusions are described in fuller detail, and are brought into sequence with the views of his many predecessors in this complex field of study.

As an introduction to the description of his own work, Dr. Head devotes a considerable proportion of his first volume to an historical review of great interest. He relates how Gall was the first to attempt to subdivide the brain into a number of separate "organs," and to place, though on fantastic grounds, the "faculty" for verbal memory in the frontal lobes. The same hypothesis was maintained by Bouillard, though he studied the phenomena of speech not so much as an intellectual "faculty," but as a form of co-ordinated movement, and he set out to prove from clinical and post-mortem observations that the tongue and other correlated organs can be paralysed for the act of speech while capable of all movements not associated with speech. Bouillard recognized that speech might be lost either from loss of control over the movements of speech or from loss of the memory of words, and he believed that both these aspects of speech were dependent on the frontal lobes of the brain for their fulfilment. He was followed by Broca, whose brilliant clinical and anatomical researches led him to implicate the third frontal convolution as the seat of the faculty of articulated speech. Broca divided clearly affections of speech of central origin into "aphemia" and "amnesia verbalis." The aphemic patient is speechless except for a few monosyllables, or for exclamations uttered under the stress of emotion; he can, however, understand what is said to him, while unable to repeat words. Such a patient is the motor aphasic of later writers. The sufferer from verbal amnesia, on the other hand, though he can pronounce words, cannot appreciate the meaning of words—that is, he has lost the special memory of both spoken and written words, and consequently cannot use words to express his ideas; he is suffering from what others have called "sensory aphasia." Broca realized that many cases did not fall clearly into the category of either "aphemia" or "amnesia verbalis," but he was emphatic that pure aphemia was dependent on destruction of the third frontal convolution on the left side. Wernicke carried the conception of sensory

aphasia further, and postulated the presence of an auditory centre for word memories in the first temporal convolution. A lesion of this centre would produce loss of "sound-images" and so lead to inability to understand spoken words. Bastian was the first to divide sensory aphasia into two forms, subsequently called "word-deafness" and "word-blindness."

Then in 1906 Pierre Marie attacked the whole doctrine of motor and sensory aphasia, denying to the third frontal convolution any direct bearing on speech. In his view there was only one form of true aphasia—namely, sensory aphasia produced by a lesion of Wernicke's zone. Broca's aphasia he regarded as sensory aphasia plus "anarthria," which was a defect of the higher articulatory aspects of speech and was dependent on a lesion of the "lenticular zone," a wide area including the internal capsule and the lenticular and caudate nuclei. Further, sensory aphasia for him consisted essentially in a loss of intellectual capacity of which the defect of speech was but a part. Perhaps the most notable contribution to the whole subject in recent years is the laborious and accurate analysis by Henschen of 1,337 cases of speech disorder, some observed personally, but for the most part carefully abstracted from the literature. His conclusions form the most advanced argument for the anatomical localization of the mechanisms underlying normal speech.

Dr. Head approached the study of the subject primarily from the psychological aspect—that is, he set out to study the forms assumed clinically by aphasia and kindred disorders of speech without reference in the first instance to anatomical and physiological considerations. He was much influenced in the course of his work by the teachings of Hughlings Jackson, with whose views he found his own conclusions to be closely in accordance. He devised a new series of tests designed to reveal the nature of the disorders of speech, and these tests he gradually formulated during the years preceding the great war. The war presented an unexampled opportunity for the observation of cases of head injury in otherwise healthy young men, a group of cases obviously superior as subjects of study to the elderly arterio-sclerotic patients more commonly suffering from these disorders in civil life.

Following this historical review comes a detailed account of his investigation of the cases and the conclusions to which he was led. The tests are designed to demonstrate, not only defects of comprehension or execution of speech, but also—and here they differ from most previous tests—degrees of such defects. For this reason the series of tests is graduated in relation to the complexity of the task which the patient is called upon to perform, and some of them extend beyond the boundaries of what is ordinarily understood by speech. To understand them it is essential to study Dr. Head's book in detail, and we can here only indicate briefly his main conclusions. They are very destructive to the older theories with which clinicians are familiar, and to which we have referred above.

For Dr. Head such terms as "aphasia" and "amnesia" are descriptive merely of abnormal forms of behaviour, and there are no "centres" for the use of language. Disorders of speech, he says, cannot be classified as affections of speaking, reading, and writing—a conclusion which will receive general assent. Further, "these disorders of language cannot be classified as motor or sensory," even in the widest sense of executive and receptive. It is here that Dr. Head is chiefly in conflict with the more conventional

<sup>1</sup> *Aphasia and Kindred Disorders of Speech*. By Henry Head, M.D., LL.D., F.R.S. In two volumes. Cambridge: The University Press, 1926. (Cr. 4to; Vol. I, pp. xiv + 519; Vol. II, pp. xxviii + 430, 63s. net the two volumes.)

conceptions, and his view does not seem to have found general acceptance by neurologists since it was first put forward in 1920. The clinician is prepared to realize that, as Dr. Head's work shows, the defects manifested as a result of disease do not necessarily indicate the elements of which normal speech is composed; also that pure forms of "motor," "auditory," or "visual" aphasia are rare or possibly non-existent. But he will be reluctant to abandon these terms as indicating broadly certain clinical types of speech affection which have a localizing value in cerebral disease. Dr. Head classifies these affections on a psychological basis into verbal, syntactical, nominal, and semantic aphasia; for the full meaning of these terms his work must be consulted. He insists that in disease speech is affected as a whole and is not divided up into the elements of which it is composed. Further, in a patient suffering from aphasia in any form, the capacity to carry out a task varies directly with its complexity, or what Hughlings Jackson calls its "propositional" value.

As a pure study of speech affections Dr. Head's work is of the deepest interest and value, and the publication of these volumes marks an important event in the evolution of our knowledge of cerebral function. Dr. Head says the results he has obtained "are of little direct practical value to the physician." This may be true, and it seems unlikely that his nomenclature of aphasia will become common currency; but everyone interested in cerebral function must study these volumes, and cannot fail to obtain much fresh light and stimulus. In particular the clinician will be led to avoid the mechanistic conceptions which have prevailed too much in the past.

## THE SCIENCE OF CLINICAL MEDICINE.

THE custom of delivering addresses to the newly entered students of the medical schools at the beginning of each winter session is at least as old as the days of Abernethy, whose discouraging greeting has been so often quoted. Of late years the custom has been discontinued at some schools, but as long as distinguished members of the profession are prepared to deliver such addresses as we print in this issue, so long will the custom survive. The occasion affords an opportunity, not only for the offer of good advice to the student, but also of placing before the lay public some facts concerning the profession, its difficulties and its aspirations, of which the public are for the most part woefully ignorant. This year we are able to congratulate ourselves on the circumstance that those two great twin brethren of medicine, the Regius Professors in the two ancient English universities, have given us the benefit of their wisdom and their experience.

In the address on "The science of clinical medicine" which Sir Archibald Garrod delivered at the Westminster Hospital he did not seek refuge in side issues, or attempt to evade the difficulties of his task under cover of a cloud of smooth generalities, but boldly faced one of the most important problems in the conduct of medical practice nowadays. In claiming that clinical medicine is as much a science as bacteriology or biochemistry he will doubtless have the approval of most, if not all, of our readers, as well as of a recent President of the Royal Society. In recommending the student to turn his attention to the laboratory Sir Archibald Garrod gave advice which should be valued and acted upon. The student cannot know too much of the ancillary sciences and studies upon which medical practice rests, but all the know-

ledge he may acquire will be of little use to him in the absence of that clinical experience which is required for successful diagnosis and treatment.

The highly technical skill needed in many laboratory tests and the time these occupy render a certain division of labour necessary in medicine, and some students are tempted by the precision and definition of the processes of investigation by means of the microscope, the test tube, and the culture medium to devote their whole attention to these instead of entering practice and coming into contact with what has been said to be the proper study of mankind. Though it must be admitted that some of the work of a busy practitioner may be tiresome, yet the bacteriologist in his laboratory also finds the repeated routine of examinations of blood and swabs and secretions dull and uninspiring, and his boredom is unrelieved by the contact with the humours, the weaknesses, and the heroism of his fellow creatures, which are continually displayed before the clinician.

It would be a great calamity if the view were to prevail that only the work of the laboratory and the study were worthy of the best intellects. Some time ago certain enthusiasts loudly proclaimed that there was no longer any need of the clinician, except as a humble collector of specimens, upon which the pathologist was to pronounce a diagnosis and prescribe the appropriate serum, antitoxin, or what not. In short, medicine was to be conducted on the principle of "You press the button and we do the rest." As Sir Archibald said, "the mere fact that a piece of work is done in a laboratory does not make it a scientific research," and, on the other hand, many of the processes by which an exact diagnosis is reached at the bedside are truly scientific.

Sir Humphry Rolleston, in his address at King's College Hospital, devoted himself more to the consideration of the careers open to qualified men, and of the course of study necessary to fit them for each, but, like his colleague and friend, he referred to the temptations to confine themselves to experimental and research work which are offered to those suitably gifted. Not only does the laboratory exercise a potent attraction on the lover of research, but the public health service also calls to those who would prefer to serve a public body and keep regular hours than be at the beck and call of all who seek their services and on duty all round the clock. To such as these Sir Humphry Rolleston pointed out how large a part is taken by general practitioners in the performance of public health duties, and stated, on the authority of Sir George Newman, that of the 1,450 medical officers of health 1,100, or over 75 per cent., are engaged in general practice. Whatever department of medicine, surgery, or pathology may be the ultimate destination of the student, he will do well when qualified to gain full experience of clinical work, especially if he aims at the public health service, in which intimate knowledge of the duties and difficulties of the practitioner, and a sympathetic consideration of them, are so important in the interest of the smooth working of hygienic regulations and their consequent efficiency. A common training as far as possible, and common experience among the sick, give the best guarantee of mutual understanding and help between the clinician, the medical officer of health, and the research worker or pathologist.

To those who think that the day of fruitful research by the practitioner outside the laboratory is past, the examples quoted by Sir Archibald Garrod should give cause for reflection. Probably the colleagues of Addison had thought that there was little more to be

found out about exhausting disease or pigmentation of the skin. Yet the connexion between symptoms and post-mortem appearances was apparent to him, and when pointed out was recognized by all. William Jenner's work on typhoid fever was equally remarkable and convincing. Both these investigators made their discoveries in the course of medical practice, and there seems no reason to despair of future discoveries at the bedside, as was shown by the late Sir James Mackenzie, who while engaged in busy practice in an industrial town found time and opportunity to use his clinical acumen in the study of heart disease, and almost revolutionized our outlook on these maladies, and especially on their prognosis, a knowledge of which is of such vital importance to the patient and his relations. Such opportunities will no doubt be less frequent than in the past, but, as the Regius Professor at Oxford reminds us in a striking simile, while it is true that the alluvial gold may have been washed out by the primitive methods of the past, yet the modern clinician is much better equipped for research than his medical forefathers, and may yet discover deep-lying deposits of precious metals. He concluded his address with a most apposite quotation from Ecclesiasticus. May we offer him in return a quotation from the same ancient fountain of wisdom? "For of the most High cometh healing, and he shall receive honour of the king. The skill of the physician shall lift up his head: and in the sight of great men he shall be in admiration" (Ecclesiasticus, xxxviii, 2-3).

#### TAXATION OF SCIENTIFIC INSTITUTIONS.

In a paper on the taxation of scientific institutions contributed to the August issue of the *Journal of the British Science Guild*, Colonel W. A. J. O'Meara has collected together many judicial decisions in a manner which throws much light on this important but little known subject. He points out that not only income tax, but also local rates and corporation duty (the tax levied on undying corporations as a set-off to their escape from death duties) may be affected. At the present level of rates and taxes the title to exemption is one of great value. Unfortunately, as the list of cases which have been before the courts shows only too well, that title is hedged about by stringent conditions, and the central and local administrations are not likely to acquiesce in any claim unless it is technically flawless. The local rating exemption clause, in the statute of 1843, is too discursive for citation, but the income-tax clause will serve as typical. Rule VI, Schedule A, provides for an allowance of "the amount of the tax charged on any building being the property of any literary or scientific institution and used solely for the purposes of that institution, in which no payment is made or demanded for any instruction there afforded by lectures or otherwise. . . ." The stringent nature of the conditions attaching to the exemption are fairly apparent, but as an illustration the case of the Royal College of Surgeons of Edinburgh may be quoted. On an appeal in 1892 the court held that, as the main objects were professional, although it promoted the advancement of science incidentally, the college was not a "scientific institution" for the purpose of the rule. In that case Lord McLaren suggested that the objects and practices of such an institution would include meeting for the discussion of subjects of science, publication of papers, and the making of grants to individuals who undertake scientific research, but he distinguished such a hypothetical institution from the one with which he was dealing. The claim in 1857 of the Royal Medical and Chirurgical

Society for exemption from rates met with a like fate, though for a different reason; in that case "the court held that the society was one established for the purposes of science exclusively, but as part of its premises were not exclusively occupied for the purposes of the society the exemption as claimed could not be supported." In 1899 the Royal College of Surgeons of England claimed exemption from corporation duty, but was unsuccessful. The fact is that exempting legislation is too frequently designed on what we may perhaps call the neck-or-nothing basis. If premises are used "solely" as scientific institutions, or if income is held on trust and is applicable to charitable purposes "only," certain allowances are given in respect of the entire premises or the whole of the income so applied; but if, say, 10 per cent. of the premises or income is applied to other purposes, however praiseworthy, the remaining 90 per cent. has to bear its full burden of taxation. We can find no justification for such a distinction other than that founded on the administrative simplicity of the present system. Scientific research and discussion must surely be more beneficial to the community when linked with practice by being organized and diffused through the agency of a professional association; and yet it is precisely this living connexion of theory with practice which seems to lead to the refusal of claims to relief from taxation. Colonel O'Meara fears that a definition of the expression "charitable purposes" by statute, as proposed by the Chancellor of the Exchequer, may curtail the existing allowances. It is surely not too much to hope that, however narrow the gate of exemption may be made, all institutional income devoted to scientific or charitable purposes will be allowed to pass through, whether it represents the whole or only a part of the total income of the society. If that change were made any possible tightening up of the statutory definition might be viewed with equanimity.

#### THROUGH OTHER EYES.

A TRIBUTE to the success of the Annual Meeting at Nottingham, and an appreciation of the present standing and aims of the British Medical Association appeared in the issue of the *Journal de Médecine de Bordeaux* dated September 10th-25th. It is by Dr. René Cruchet, professor of pathology and general therapeutics in the University of Bordeaux, who made a communication to the Section of Medicine at Nottingham on his experimental study of blood transfusion in man and animals; this paper we shall publish in a later issue with the proceedings of the second day of the Section. He took advantage of his brief stay in England to pay a visit to the house of the Association in Tavistock Square, and his abiding interest in research led him to investigate also what might have been called the circulatory system of the Association, were it not that the title of his article in our *Bordeaux* contemporary is "*Affaire de mentalité*." He recalls with a touch of sadness the fact that societies for medical defence and co-operation were in existence in France at the time when the British Medical Association was born, but, though these French societies united in 1841, the resulting organization has been gradually failing in strength and in its representative character. This decline he attributes to its fixation to a tradition, and the consequent failure to develop conformably with its changing environment: a failure especially regrettable now that individualism in medicine is in danger of being lost in syndicalism. Viewed through his eyes the happier lot of the British Medical Association is due to our recognizing that what we may lack individually, as compared with our French colleagues, has been more than compensated by our greater genius for developing *esprit de corps* and *esprit de suite*. So, while in France readjustment of

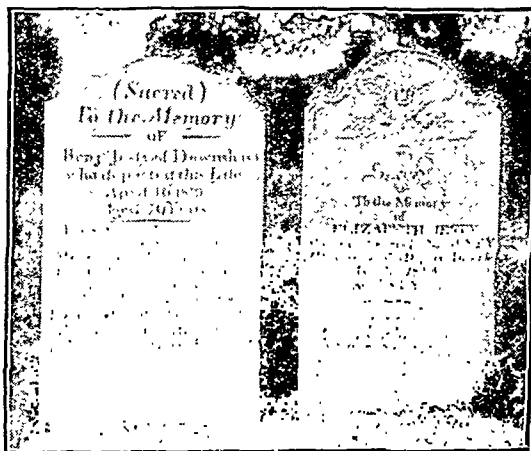

the profession to new demands takes the form of short jumps, there is, he finds, in England a gradual daily adaptation and a patient unwearying struggle, due (to use his own metaphor) to the existence of a frame which remains the same, while the picture it contains is retouched according to the needs of the time. To its service in this important respect he attributes the growth of the British Medical Association. Elsewhere in the same issue of our contemporary Professor Cruchet discourses at length upon the Nottingham meeting, and indicates the evidence for his belief that the Association truly represents the medical body in its relations to the community and to Parliament. Mr. Hogarth's Presidential Address particularly appealed to him, as did the way in which medico-political problems were considered. In acknowledging Professor Cruchet's warm congratulations it may be added that, besides the privilege of welcoming him personally in Nottingham and in London, we were also, as he suggests, conscious of the honour of receiving a representative of the renowned University of Bordeaux, whose past fame is being augmented in our day by the researches of its living members.

#### THE CHINA MEDICAL ASSOCIATION.

The eighteenth biennial conference of the China Medical Association was held at Peking from August 31st to September 8th. This association, previously well known as the China Medical Missionary Association, has now widened its basis, and the reports of the various councils and committees submitted to the general meeting indicate the extent of the organizing and administrative work that is being undertaken. The previous conference in Hong-Kong, in the early part of 1925, adopted a new constitution which accompanied the alteration of name; it is stated that the changes then made have proved to be satisfactory, despite the fact that in the short period of rather over one year the association has been deprived of the services of Dr. S. Cochran, the president; Dr. W. C. Grosvenor, the vice-president; and Dr. E. M. Merrins, the editor of the *China Medical Journal*, which is the monthly periodical of the association. One committee has been engaged upon the proposed registration and grading of hospitals, and has attempted to define the minimum requirements for registration, including regulations dealing with the professional and non-professional staffs, the provision of suitable wards, operating theatres, pathological laboratories, dispensaries, and residential accommodation, together with the use of the hospital records prescribed by the association, or of approved equivalents. During the last five years the work of the association has received substantial financial support from the China Medical Board of the Rockefeller Foundation. The clinical side of the conference was divided into eleven sections, and abstracts of numerous papers there read were combined and published in a small pamphlet. Malaria was discussed by Dr. E. C. Faust, who dealt with its general prevalence; by Dr. K. H. Li, who defined the part to be played by mission hospitals in research, prophylaxis, and treatment; and by Drs. H. E. McIneny, C. U. Lee, and K. L. Chang, who described a preliminary survey of the distribution of anophelines in the neighbourhood of Peking. Reports of amoebic abscesses of the liver were given by Drs. A. I. Ludlow and G. W. Van Gorder. The subjects for discussion in the obstetrical and gynaecological section included eclampsia, contraception, ectopic endometrial tissue, and the use of the blood sedimentation test in the puerperium. The section of hygiene and public health considered the maternity problem in China, venereal diseases, public health, nursing, and child mortality. In connexion with the conference numerous excursions and entertainments were arranged.

#### BENJAMIN JESTY'S GRAVE.

THE Jenner Centenary Number of the *BRITISH MEDICAL JOURNAL*, published on May 23rd, 1896, besides much other historical matter, included a note on the precursors of Jenner. The milkmaids in Gloucestershire and elsewhere had found out for themselves that cow-pox was a safeguard against small-pox before the insight and patient labour of Jenner transformed a piece of folklore into a scientific truth and made the medical profession all over the world receive it as such. Nor was he the first to inoculate cow-pox with the object of giving protection against small-pox. The first vaccinations of which there is any record were performed by Benjamin Jesty, a farmer of Yetminster in Dorset, who in 1774 inoculated his wife and two sons, aged respectively 3 and 2 years. He himself had had cow-pox before by contagion from the cow. His vaccinations were successful, and his family remained proof against small-pox inoculation and contagion. Again, in 1791 Peter Plett, of Schönwaide in Holstein, successfully vaccinated some children. Neither Jesty nor Plett, however, seems to have followed up the matter; hence nothing came of their

happy thought. They had a glimpse of the truth, but they passed away and left no trace. It was on May 14th, 1796, that Jenner carried out his first inoculation with cow-pox. We have lately received from Dr. C. H. F. Johnston of Frome an interesting photograph, taken during his holiday this summer, of the tombstones of Jesty and his wife at Worth Matravers in Dorset. The inscription on Benjamin Jesty's tombstone runs as follows: "Sacred to the memory of Benjm. Jesty of Downshay, who departed this life, April 16th, 1816, aged 79 years. He was born at Yetminster in this county, and was an upright honest man, particularly noted for having been the first person (known) that introduced the cow-pox by inoculation, and who from his great strength of mind made the experiment from the cow on his wife and two sons in the year 1774." The other tombstone says that his wife Elizabeth died on January 8th, 1824, aged 84 years.

#### DIETETIC TREATMENT OF PERNICIOUS ANAEMIA.

WHEN there are many forms of treatment for a disease the results of any one are usually disappointing. Pernicious or Addisonian anaemia (as the Guy's school, who, following tradition, have, under the wise leadership of Dr. A. F. Hurst, done so much lately to advance our knowledge of the disease, piously prefer to call it) has apparently become much commoner; whereas chlorosis, in which the treatment by iron was so eminently successful, has become a much sought after clinical curiosity. Of the methods of

treatment in Addisonian anaemia arsenic and hydrochloric acid are recognized as the most successful, splenectomy, after a comparatively brief period, has largely dropped out, and transfusion is losing ground. Recently two papers have drawn attention to the importance of dietetic treatment, and certainly deserve attention, for the basis on which the recommendations are made does not run counter to the present conception of the importance of the absence of hydrochloric acid in the gastric juice. Minot and Murphy,<sup>1</sup> after summarizing the various dietetic methods of treatment in the past, such as high protein content, a restricted fat content, and a vegetable and fruitarian diet rich in iron, give an account of the treatment of forty-five patients on a diet with an abundance of food rich in iron and purine derivatives, and proteins, particularly liver, much fruit and fresh vegetables, and relatively low in fat. The special diet consists of calf's or cow's liver 250 grams or more, beef or mutton 120 grams or more, vegetables at least 300 grams, fruit 250 to 500 grams, cream and butter 40 grams, if desired an egg, and milk 240 grams, and potatoes or cereals to make up 2,000 to 3,000 calories. The rationale of the diet is discussed at some length. The value of liver in regenerating the blood has been shown experimentally by Whipple and Robschey-Robbins, and the nutritional value of liver is the same as that of red bone marrow, which has been used therapeutically in the past. There is some evidence that fats increase intestinal putrefaction, and so are undesirable; the vegetable ration is recommended on account of its iron content, and the good effect of strawberries in sprue, a disease in some respects resembling Addisonian anaemia, is noted, but the question of vitamins is only just mentioned. Patients placed on this diet rapidly improved both as regards symptoms, except those with subacute combined degeneration of the cord, and as regards the blood; thus patients with an average red count of 1,470,000 before the diet was commenced showed an average of 3,400,000 after a month, and in twenty-seven instances in which the diet was continued from four to six months the count averaged 4,500,000. The young reticulated cells in the blood are temporarily increased, and the icterus index of the blood serum falls. It remains to be seen whether or not the remissions in these forty-five cases will last longer than in a control series. In a research based on experimental observations Koessler, Maurer, and Loughlin,<sup>2</sup> while accepting the influence of achlorhydria in favouring the formation of haemolytic, myelotoxic, and neurotoxic bodies, believe that these are only able to pass through the intestinal wall and do damage when the cells of the intestinal mucosa and perhaps of the liver are altered by a long-standing deficiency in vitamin A (and perhaps also of B and C) due to improper feeding. A condition similar to Addisonian anaemia was induced in rats by a diet deficient in vitamin A. The diet recommended for the treatment of Addisonian and aplastic anaemia in man is especially rich in vitamins A, B, and C, and should be ample and of high calorie value: milk 1,500 grams, cod-liver oil 20 grams, cream 100 grams, butter 60 grams, two or three eggs, and 100 grams each of oranges, tomatoes, lettuce, spinach, meat (liver, kidney, sweetbread, or brain), and bread. Of the meats, liver and kidney contain the largest amount of vitamins A and B, and probably also some vitamin C. The authors insist on the administration of hydrochloric acid in increasingly large amounts, and also of yeast. Comparison of this diet with that recommended by Minot and Murphy shows a divergence as regards the fat intake, but it should be mentioned that Minot and Murphy considered that the low fat content of their diet was much less important than the character and amount of the protein. But though con-

structed on different logical grounds, the mode of action of Minot and Murphy's special diet—namely, liver, which is rich in vitamin A, and plenty of fresh fruit—may therefore merely be that it is a method of supplying the required quantity of vitamins.

#### INTERNATIONAL PORT SANITATION.

A PARTY of medical officers concerned with the sanitary administration of ports in the Baltic, North Sea, and English Channel are at present in this country. The visit is opportune in view of the fact that a new international sanitary convention was signed in Paris last May by over fifty nations, covering practically all the chief ports of the world. This convention is the final outcome of a series of international conferences dating from 1851, when an attempt was first made to unify the quarantine laws in Europe. A number of other conferences were held and conventions signed, and in 1907 a central international health office was established in Paris to study the various conventions and to prepare for their amendment to meet new knowledge, new conditions of commerce, and new political circumstances. The convention of this year was drafted by that office, and is a very thorough revision of the international measures needed to prevent, in particular, the spread of cholera, yellow fever, typhus fever, and small-pox. With this new basis of international understanding it has become necessary for all port health authorities to overhaul their methods, and the League of Nations has therefore done very well to take advantage of the financial assistance of the Rockefeller Foundation to extend to this subject the interchange system which, as our readers are aware, has been applied on many occasions during recent years to other aspects of public health administration. The party arrived at Southampton on Monday last; there they were received by the mayor and Dr. Lauder, medical officer of health for the borough and port. They were shown the disinfecting station, the V.D. clinic, the infectious disease hospital, and the docks. On Tuesday they passed through London, and were received at the Ministry of Health, where Sir George Newman delivered an address and Dr. H. A. MacEwen, one of the senior medical officers of the Ministry, gave an outline of the arrangements for port sanitation in this country. Afterwards the members of the party were entertained by the British Government at a luncheon, over which Sir H. Kingsley Wood, M.P., Parliamentary Secretary to the Ministry of Health, presided, and on the part of the Government extended a warm welcome to them. Dr. Jitta, president of the Health Council of the Netherlands, and one of the representatives of the Health Committee of the League of Nations, made a suitable reply. In the afternoon the party went to Liverpool, where they spent two days and were shown the general arrangements of the port. They made a trip up the River Mersey, and witnessed a demonstration of rat-catching and of various methods for the destruction of rats. Visits were also paid to the cold stores and warehouses, and to the isolation hospitals of the borough and port sanitary authority. On the following day the party visited the immigration hostel, the V.D. department of the Seamen's Hospital, and the School of Hygiene. After being entertained at lunch by the Lord Mayor they returned to London, where, according to arrangement, Dr. W. M. Willoughby, medical officer to the Port of London, was to act as guide in an inspection of the system of boarding vessels at Gravesend, and on visits to the Port Sanitary Hospital, and to the warehouses and cold stores at the Royal Albert Dock. On Saturday, before leaving for Geneva, the party were to see the museums of the School of Tropical Medicine and the Royal Sanitary Institute, and to be entertained at luncheon at the Guildhall. The countries represented were Belgium, Denmark, Finland, France, Germany, Latvia, Lithuania, the Netherlands, Norway, Sweden, Russia, and the Free City of Danzig.

## SCANDINAVIAN NEUROLOGICAL CONGRESS.

THE third Scandinavian neurological congress was held in Oslo on September 17th and 18th, under the presidency of Professor G. H. Monrad-Krohn. The first day was entirely devoted to neuro-syphilis, a paper of considerable interest being contributed by Professor H. Dahlström of Stockholm, who stated that quaternary syphilis was exceedingly rare amongst patients treated without the use of mercury according to the principles of the late Professor Boeck of Oslo. Subjects dealt with on the second day included the relation of epidemic encephalitis to epidemic parotitis, ventriculography and cerebral operations, and the physiology of binocular vision. One speaker claimed that a disease apparently identical with Huntington's chorea had been observed and described by a local practitioner in Norway many years before Huntington. It was decided that the fourth Scandinavian neurological congress should be held in Helsingfors in 1929.

## SIR NEVILLE HOWSE, V.C., K.C.B., K.C.M.G.

Among the delegates to the British Imperial Conference is a distinguished member of the medical profession, Major-General Sir Neville Reginald Howse, who has been Minister of Defence and Health in the Australian Commonwealth for more than a year, and a member of the House of Representatives since 1922. Sir Neville Howse, who was born in Somerset in 1863, is the son of the late Dr. Alfred Howse; he received his medical education at the London Hospital, and obtained the M.R.C.S. diploma in 1895 and the F.R.C.S. in 1897. He served in the South African war from 1900 to 1902, receiving the Queen's medal with six clasps and the King's medal with two clasps. In 1901 he was awarded the Victoria Cross for conspicuous bravery during the action at Vredfort on July 24th of the previous year, when he went out under a heavy cross-fire and picked up a wounded man and carried him to a place of shelter. During the late war he was principal medical officer to the Australian Naval and Military Expedition to German New Guinea and the Pacific Islands, and held the appointments of A.D.M.S. 1st Australian Division, D.M.S. Australian Imperial Force, and D.G.M.S. Australian Military Forces. He served with the Australian army during the Dardanelles operations, and received the C.B. in 1915; he was promoted K.C.B. in 1917, and appointed K.C.M.G. in 1919. He was an Australian representative at the League of Nations Assembly in 1923.

## MEDICAL SOCIETY OF LONDON.

THE programme for the first half of the 154th session of the Medical Society of London has now been issued. At the annual general meeting on Monday, October 11th, the Fothergillian Medal will be presented by the new President, Sir Humphry Rolleston, Bt., to Sir Frederick Gowland Hopkins, F.R.S., professor of biochemistry in the University of Cambridge, and at 9 o'clock the Annual Oration (postponed from May 10th owing to the general strike) will be delivered by Sir Berkeley Moynihan, Bt., President of the Royal College of Surgeons of England, whose subject is "Before and after operation." The Oration will be followed by a conversazione. A clinical evening will be held at 8 o'clock on October 25th, and the three following meetings will be devoted to general discussions, all beginning at half-past eight. On November 8th the subject of "Sternal pain" will be introduced by Dr. John Parkinson and Mr. A. J. Walton; on November 22nd "Recent advances in the treatment and diagnosis of bronchiectasis," by Dr. Clive Riviere and Mr. J. E. H. Roberts; and on December 15th "Recent advances in the etiology, diagnosis, prophylaxis, and treatment of the exanthemata," by Dr. J. D. Rolleston and Dr. R. A. O'Brien. The Lettsomian Lectures, on "The surgery of the spinal cord and membranes," will be delivered by Mr. Donald Armour.

## THE TERCENTENARY OF FRANCIS BACON.

THE tercentenary of Francis Bacon (1561-1626) was celebrated at Cambridge on October 5th by a special degree congregation, a large garden party in the grounds of Trinity College, and a commemorative lecture in the Senate House by Dr. C. D. Broad, Fellow of Trinity, on the philosophy of Francis Bacon. The congregation was presided over by the Earl of Balfour, Chancellor of the University, who conferred the honorary degree of LL.D. on Dr. W. S. Holdsworth, K.C., Vinerian Professor of English Law at Oxford, and that of Sc.D. on Sir Ernest Rutherford, O.M., P.R.S., Cavendish Professor of Experimental Physics at Cambridge, thus commemorating Bacon's eminence in law and in natural philosophy. The guests at the garden party were received by the Master (Sir J. J. Thomson, O.M.) and the Vice-Master (Dr. St. John Parry) of Trinity and in the College Library rare first editions of Bacon's works were on view.

## A VETERAN OF LARYNGOLOGY.

PROFESSOR E. SCHMIEGELOW of Copenhagen celebrates his seventieth birthday on October 13th, and retires from active service as chief of the oto-laryngological clinic at the Rigshospital (University of Copenhagen). His friends in many countries are marking the occasion by presenting to the clinic a medallion portrait of the professor in bronze. The Royal Society of Medicine will be represented by Sir St. Clair Thomson, Past-President, who will make a contribution to the meeting of the Danish Oto-laryngological Society to be held on October 12th. Addresses will also be given by Professor Burger (Amsterdam), Professor von Eicken (Berlin), and other European leaders who will unite in doing honour to the doyen of Danish oto-laryngology. Professor Schmiegelow was a pioneer in his subject. He studied under Morell Mackenzie at the Throat Hospital in Golden Square, and he has been a frequent visitor to this country, where he has many admirers and friends.

THE Harveian Oration will be delivered before the Royal College of Physicians of London by the President, Sir John Rose Bradford, K.C.M.G., F.R.S., on Monday, October 18th, at 4 o'clock. The annual sermon at the Church of St. Mary-le-Bow, re-established under the scheme of the Charity Commissioners for the administration of the Sadleir Trust, will be preached at 11 a.m. on the same day.

THE Lloyd Roberts Lecture will be delivered this year on Friday, November 19th, at 5 o'clock, at the Royal College of Physicians of London, by the Very Rev. W. R. Inge, D.D., Dean of St. Paul's.

THE museum demonstrations at the Royal College of Surgeons of England will begin on Friday, October 15th, when Sir Arthur Keith, F.R.S., will demonstrate specimens recently added to the museum. His second demonstration, on the following Friday (October 22nd), will be on the anatomy of the sacro-iliac region and its application to practice; and his third, on Friday, October 29th, on disorders in the growth of bone. Mr. C. E. Shattock's demonstrations, to be given on Mondays, October 18th and 25th, will deal with surgical conditions of the lymphatic gland, and of blood vessels; his third demonstration, on November 1st, will be on scrotal tumours. The demonstrations will be given at 5 p.m. on each day.

## Opening of the Winter Session.

### THE FUTURE OF WOMEN IN MEDICINE.

Address to the London School of Medicine for Women.

BY

SIR WALTER FLETCHER, K.B.E., M.D., D.Sc.,  
LL.D., F.R.S.,

Secretary of the Medical Research Council.

AFTER paying a warm tribute to the work and character of the late Dr. J. G. Adami, who was to have delivered the introductory address, Sir Walter Fletcher said:

Our chief object, I take it, to-day is to greet and cheer your members now beginning work here and to welcome them into the common fellowship of work and study in this place. To do that is both easy and agreeable, and, if I am to be spokesman, may I in your name congratulate your freshmen upon entering their apprenticeship to a profession which has so much to claim and so much to offer for any who join it with the right qualities of mind and heart.

But it is expected that our greeting should be coupled with some kind of friendly admonition or advice, and it is here I feel that the difficulty begins. I am not troubled by the general dubiety of giving advice. You will remember Lord Morley held that there were two kinds of fool in the world—those who give advice and those who take it. We can evade that condemnation by giving, not direct advice, but helpful information. Yet what accurate information about the coming years can we now give to inquiring beginners? What the freshman now seeks, surely, is information about the probable professional opportunities open to her in the early and distant future, so that she may take the best way to making the most of her powers. The difficulty of helping her is the difficulty of forecasting the future, and I think that the problems here are more pressing and more puzzling at the present time than ever in the past. We are faced by two sets of problems: those which belong to all medical education, and those special problems which belong to women as such.

#### General Problems of Medical Education.

The very rapid development of science in the past generation and its growing application to medical practice are making it year by year more difficult to predict the course which medical practice is likely to follow in its next progress and to direct the lines of medical education more fitly to their ends. Great changes are taking place, and the rate of change is likely to become more rapid rather than more slow. The progress of surgery, of which the development in the last generation has been so phenomenal, seems likely now to follow the law of diminishing returns and to be approaching something like stability. If science indeed could give us preventive control over cancer, the volume of surgery would at once be immensely reduced. It is not very bold, again, to think that the physician is likely to find his powers and scope changing rapidly in many ways as we lay hold of the elements of a scientific knowledge of nutrition and begin to use its enormous latent powers. The work of preventive medicine in all its branches is in a period of great expansion, and many new forces are now at work which will open up the possibilities of extending this throughout the Empire and of removing the long-standing waste and disgrace of preventable but unprevented disease under the British flag. The growth of biochemistry holds obviously untold possibilities, some almost within our grasp, which, when applied to human affairs, may deeply affect the future of medicine, and indeed may bring startling changes to the whole of our social structure. In large and in detail the problems of the kind thus briefly indicated must be in the minds of all those who are serious about medical education.

#### Problems of Women's Medical Education.

All these general considerations, of course, are relevant to women's education no less than to that of men. But

I would venture to urge now that there are problems of women's education in medicine which are not the same problems as those for men, and that women should resist the present assumption that their medical education should follow exactly the lines laid down for men, and that their outlook towards their future practical work should be the same. Hitherto the medical education of women has followed in almost every detail the traditions and practice evolved for men. This has been an historical necessity. The early pioneers of women's medical education had no choice. I need not in this place touch on the history of this great movement, so well known to all here. It was a movement some of whose great leaders have their names enshrined for ever in this school. "*Si monumentum requiris circumspecte.*"

The battle now, however, has been fought and won, and almost complete freedom has been gained for the future development of women's medical education. The time seems to have come when close parallelism at every stage of the medical education of men and women should no longer be assumed. Better reasons at least must be found for it than custom and convenience, which sprang from older necessity. It may be that to maintain too close a parallelism is wasteful and even disastrous. As biologists we cannot fail to be awake to this. "Male and female created He them." We should be slow to think that the very best powers of a woman can be developed and employed by following exactly the same course and by working in just the same fields as those in which the best powers of a man may be brought out. We must believe that the highest service of each will be given in differentiation of function, and that co-operation between man and woman, each working in the best sphere, is to be far preferred over rivalry. Closer adaptation of the nature of the work to the qualities of the workers by no means involves any inequality or any lowering of intellectual standards. On the contrary, it is likely to call for higher standards on each side and to give room for effort which will be more effective because it will be more intensive.

I touch upon these problems here with the greatest diffidence. I am much more certain of their existence and importance than I am of the right way to their solution. When I speak of divergence or differentiation in the educational courses to be followed by men and by women, I am thinking, of course, of the whole period of training, and more especially of the post-graduate training. How far, at what points, or if at all, there should be a difference in the minimum courses for qualification are problems not now considered. I am thinking rather of what a woman student should be inclined or recommended to select than of what she should be made to do by regulation.

#### Fields of Work for Women.

In this matter we should think first of the fields of work specially appropriate to either sex, and, without looking at all closely now, to see where the exact boundaries of the fields may lie. It seems to me obvious that the rough and tumble, if I may use those words, of general practice make it much less suitable as a general rule for women than for men. It seems evident, too, that only exceptional women are likely to join with men on equal terms in specialized surgery. It will be long, to give another instance, before medical work in the tropical and many other parts of the Empire will be so suitable for women as for men.

On the other hand, there are large fields of service calling peculiarly for the special gifts of women, in which it seems to me that they could give far more abundant and more progressive service than is given now. I think here specially of the study of nutrition, of children's diseases, and of maternity in all its phases. Here are immense fields offering problems of the greatest interest, and giving opportunities for service of inestimable value both to the individual and to the nation. Closely linked with these are the possibilities of work in preventive

medicine, in the study and management of child welfare, whether in the city, in the school, or in the factory, and in all the applications of physiology and medicine to the lives of women and children engaged in industrial work.

I said earlier that the first beginnings of our knowledge of nutrition were already promising to affect deeply the practice of medicine. Is not this a direction in which women should strive to make themselves, so to speak, mistresses in their own house? It happens here that much of the basic knowledge we are beginning to collect has been gained in the laboratory by medical women and by non-medical women. Miss Chick and her colleagues at the Lister Institute has given invaluable service here by work, more particularly, upon the several vitamins. They gave help of the first importance to our naval and military forces during the war by their work upon the anti-scurvy vitamin (C) and the vitamin B. Miss Chick again and her colleagues, Miss Hume and Miss Henderson Smith, together with Dr. Dalyell and Dr. Helen Mackay of this school as clinicians, made valuable studies of rickets in Vienna from 1919-1922, and to this expedition we owe, among other things, the first experimental demonstration that ultraviolet light and the vitamin of cod-liver oil are interchangeable in the prevention or cure of rickets in babies. In the past year Miss Chick, with Miss Roscoe, has shown, by refined and laborious experiments, that the growth vitamin A, and the antirickets vitamin D, for their abundance or deficiency in cow's milk depend upon the diet of the cow and its access to sunlight. The growth vitamin depends solely upon the supply of vitamin in the cow's fodder. The cow can only transmit it. But the antirickets vitamin, though it may be supplied in the fodder and transmitted by the cow, may also be manufactured afresh in the cow's body under the influence of sunlight. When we think of the dependence of our industrial populations upon the milk of cows commonly stalled and kept in the dark, we can realize the inestimable practical value of new knowledge of this sort.

Another woman, again, and another non-medical woman, Mrs. Mellanby, in following up her husband's pioneer work upon rickets as a deficiency disease, has revealed a fundamental relation between the diet before and during dentition and the formation of teeth, the effects of vitamin deficiency being shown both in damage to their general structure and arrangement and in failure of their minute, invisible architecture—that prismatic architecture of the enamel which gives it hardness and its resistance to disease. It seems likely that this discovery will not only transform our outlook on the national problem of dental decay, but give us the true key to its practical solution.

All these studies and others like them give ground for confident hope of an immense increase in our practical powers of repelling disease and of increasing the happiness and the beauty of our people. Research here is costly, painful, and slow, yet the due application in effective practice even of the little we already know seems often to be slower still.

The new knowledge of the vitamins of milk which we owe to Miss Chick and her colleagues has immediate relevance to the problems of human lactation, to the treatment of the expectant and nursing mother, and the management of breast-feeding. This seems to be a field crying aloud for the better attention of women. If the truth were known, I venture to think that my sex has done far too little in the proper advocacy of breast-feeding; men have tended, I am afraid, to throw their influence in fact, if not on paper, rather on the other and the wrong side. But even with the better knowledge and the better weapons that research has given, a man, after all, can only know and apply the physiology of lactation. A woman may know both its physiology and its psychology, and without a knowledge of both the physician is incomplete.

The application of nutritional study to medical practice, whether curative or preventive, surely offers a field of work peculiarly fitted for women. It is not a soft option. It calls for arduous work and highly technical study; it offers problems of great intellectual interest, and at the same time promises high rewards in practical usefulness. In spite of this, however, it does not seem that any signifi-

ficant body of medical women are turning their special attention in this direction.

This seems in itself to be a phenomenon worth examining. I would ask you to allow me to touch here upon a point which may possibly have some relevant connexion with it. I will put a bold question, and hope that you may forgive my candour. Why is it that women following a communal intellectual life are so prone to neglect both the quantity and the quality of their own food? It is notorious that, speaking generally, women's colleges and other institutions governed by women provide food which is often inadequate in amount, badly chosen, badly cooked, and badly served! All men who have sisters or daughters at college or some similar place become aware of this. It is not enough to say that women are less greedy than men. The deficiencies I have in mind often take the diet below the minimum for due nourishment, while bad cooking is at least as wasteful and indefensible as greed itself. I venture myself to think that the phenomenon I describe, now perhaps beginning to disappear, was originally due to the intellectual fervour of the movement for women's higher education, and that in the pursuit of high thinking plain living was allowed to become bad living. Here has been a great opportunity for medical women, and I believe that enlightened action from your professional side has still immense potency for helping the nation by improving the food and the health of the very girls and women upon whom our best hopes for the national future depends.

#### *The Factor of Marriage.*

May I finally touch upon one consideration which must be borne in mind in all discussions of divergence between the medical courses of men and women? The high function of marriage rarely takes a man out of the profession; it must, on the other hand, in most or many instances remove a woman from practice. This elementary difference is inevitably a large factor in decisions that have to be made when men and women students stand together in competition for educational facilities within hospitals or elsewhere. Time and money spent upon, say, ten men will go to make nearly ten future doctors. The same effort spent upon ten women must give a far smaller future effective output. I hold myself that few, if any, schemes of education are better than a sound medical education as a preparation and equipment for marriage. It should guide and strengthen a woman to perform "justly and skilfully and magnanimously" all the high and all the lowly tasks of married life. I think a wise student will see to it that in the absence of special reasons she will try to emphasize in her professional training and work those parts of the subject not only best fitted for a woman if she remains in professional practice, but most likely to be serviceable if and when marriage comes to her afterwards.

I know well that I have touched upon several points still the subject of high controversy. Yet it is those who are most in earnest about the future of women in medicine who will be the most desirous that these problems should be raised fearlessly, and that they should find their discussion and their right solution at a place like this, so rich already in the highest traditions of work and service.

### THE MEDICAL PROFESSION AND THE PUBLIC.

#### ADDRESS BY DR. GRAHAM LITTLE AT ST. GEORGE'S HOSPITAL.

AFTER distributing the prizes at St. George's Hospital Medical School on October 1st, Dr. E. GRAHAM LITTLE, M.P., gave some reminiscences of the institution which he left thirty years ago, and in particular of Howship Dickinson, whose clerk he was. One of the useful lessons taught him by Dickinson was that redundancy did not mean emphasis. If he wrote that the extremities were cyanosed and blue, Dickinson insisted on the deletion of one or other of the adjectives.

For the main theme of his address Dr. Graham Little took as his text some comments on medical education and ethics which appeared in a letter addressed to the *Times* in October last by Mr. Bernard Shaw. Mr. Shaw was

handicapped—but, of course, not deterred—by a complete ignorance of the subject he criticized, and perhaps for that reason he was typical of a great mass of public opinion which the profession would do well to recognize as dissatisfied with many of the circumstances attending the practice of medicine to-day. Mr. Shaw wrote that the General Medical Council had become a trade union of the worst type, deliberately addressing itself to the antisocial task of preventing the public from calling in an unregistered practitioner who was in competition with those on the *Register*; he also condemned as obsolete the training maintained by the General Medical Council, and implied that it was ill designed to meet the needs of the public and compared unfavourably with the training—if that word could be used—in some branches of unqualified practice.

#### *The Medical Curriculum.*

In rebutting these criticisms, Dr. Little pointed out that the period required for entrance into the medical profession was more than twice as long as that required for entrance into any other. Demands were constantly made for new additions to the curriculum. It was quite certain, whatever readjustments might be advisable, that the teaching in anatomy and physiology could not be shortened, for this was the basis of scientific medicine. Again, the General Medical Council had wisely placed in the very forefront of its resolutions of 1922 with regard to professional education that throughout the whole period of study the attention of the student should be directed by his teachers to the importance of the preventive aspects of medicine. The same resolutions recommended that a minimum period of three years—in practice more usually four—should be available for clinical studies. It was upon this clinical training that the great English school had founded its prestige. In a conversation he had had with the adviser to the Carnegie Foundation, that very astute gentleman declared that in the practical art of medicine the British medical contingent in the war far excelled that of every other of the belligerent armies, including his own. — It was precisely in the preposterous neglect of clinical study and the lack of opportunities for pursuing it that the unqualified practitioners compared so very unfavourably with the graduates of the orthodox medical schools. In the United States the largest osteopathic college, with 1,000 students, was situated in a small frontier town in Missouri with a population, including the students, of 4,000. Presumably the students found their clinical material in each other! Compare this with Oxford and Cambridge. Each of these universities was in a town of some 60,000 inhabitants, and yet they regarded the local clinical material as inadequate, and the medical students were sent to London schools for their clinical work.

The curriculum was growing with every decade, and the minimum period of study to secure qualification was stretched well into seven years. Notwithstanding this, the public journals clamoured for more subjects to be included. The *Times* had gravely urged the inclusion of osteopathy and psychology. There was no finality visible in the burden to be laid on the coming student generation. Signs, however, were not wanting that in this matter of the curriculum the breaking point was being approached, and the encouragement given by an unthinking public to unqualified practice was hastening that consummation. If an osteopath, after a period of very imperfect education in the medical sciences, ranging from one to four years, was given, as some desired, the privileges now accorded to medical men with their seven years of rigorous professional study, who would be fool enough to take the severer course?

#### *Unqualified Practice.*

Great Britain stood nearly alone—the only other notable exception was Germany—in the encouragement which its Legislature gave to unqualified practice. In this country a man might pursue unqualified practice without penalty unless, indeed, he falsely laid claim to titles and qualifications and some person was public-spirited enough to take the matter up. And when to this was added the publicity to be derived from advertisement, denied to the qualified man, surely the dice were loaded against the latter. And all this time medical education tended to be more and more

extended. There had never been a period when the scientific preparation for the practice of medicine was so necessary. There was an ever-reaching public demand for new subjects of study. But if the public refused to differentiate the finished product of all this preparation from the shoddy result of a pretentious imitation thereof, the genuine product could not be maintained. The remarkable enlistment of new recruits to the profession following the war had passed its high-water mark. No doubt the incomparable human interest which the practice of medicine involved would, for some time at least, attract the best class of student, but it might be that a day would come when the supply of scientific doctors would give out, and their place would be taken by money-grubbing and imperfectly educated quacks ever seeking a back door of entry into the fold. It might be that orthodox—that is, scientific—medicine would be replaced by a system which had been euphemistically described as “drugless medicine and bloodless surgery.” Imagine the practitioner of such a system confronted with any one of the four great scourges of humanity—malaria, tuberculosis, cancer, syphilis!

Unfortunately, there was no indication of public support for the curtailment of the privileges of the unqualified. Nowhere had the quacks more friends than in the House of Commons, to judge from his personal experience when bringing forward his motion in February last for the regulation of unqualified practice. In that very interesting debate it was amazing to find it assumed in speech after speech that the advances in medicine had come invariably from extra-professional sources. The public, in fact, were unaware of the immense strides in medical science during the last thirty years, which Professor Starling had described, not as a renaissance, but as a new birth. The medical discoveries in that period had been far more often made by men in the medical profession than by men outside. True, Pasteur was constantly being cited, but it was Lister who saw the full meaning for surgery of Pasteur's discoveries, and without Lister Pasteur might very well have gone unheeded by medicine.

#### *Doctors and the Press.*

The press, Dr. Graham Little continued, had conducted a very insistent campaign for removing the restrictions which now prevented medical men from writing for newspapers under their own signatures. The General Medical Council was often unfairly saddled with censure for these restrictions. It was really bodies like the British Medical Association which exercised pressure to prevent covert advertising to which such communications might lead. The press could not be wholly disinterested in this matter. It was obviously to its interest to get hold of good “copy,” though it was difficult to think that the essays in the *obvious* or the sheer balderdash published under “Health Notes” could be acceptable to any intelligence, however feeble. The activities of the New Health Society did not convey the impression that the writers empanelled for its purposes were among the inspired prophets of our times. Not long ago one of the tearshops blossomed out with the announcement that the President of the New Health Society and his band of experts had contributed a scientific menu for the athlete. The menu was provided in the tearshops specified, but an examination by a medical writer of the items of this “food for heroes” disclosed no very great variation from the bills of fare provided by other tearshops. Sausages and buns figured largely. The printing of the photograph of the distinguished president added materially to the amusement of the public and the amazement of the profession. But it was obvious that this was not the way to approach a really serious problem—the problem, namely, of disseminating by the very potent influence of the press really sound and expert information which might be actually useful for uninstructed persons. This question was to be fully discussed at a meeting of the St. Pancras Division of the British Medical Association on October 12th, and he would leave it in far more capable hands than his own.

#### *The General Medical Council.*

With regard to the General Medical Council, a statutory body, it was evident that Mr. Bernard Shaw, like so many laymen, confused it with the British Medical Association.

The British Medical Association was a private body, with as much right to make rules for its members as the committee of a club, and those who did not like to obey had the opportunity of resigning from its membership.

Scientific medicine had advanced *pari passu* with the setting up of the General Medical Council, and as for the disciplinary functions of the Council, the profession and not the public was the best judge as to what degree of control medical men would and should accept. In the matter of advertisement the Stock Exchange exacted a self-denying ordinance against its members advertising—an ordinance which was clearly of public utility—and medical men should surely enjoy the same privilege of ordering their affairs in this respect. Open advertisement would probably be resented as much by the public as it would be disliked by the reputable medical man. In dealing with covert advertisement it was more difficult to differentiate what was legitimate from what was undesirable, but no doubt a *via media* could be found. The activities of the Council in restraining the association of registered practitioners with unqualified persons were also misunderstood. It should be emphasized that the offence known as "covering" might be actually dangerous to the public, and it was from this standpoint that the Council had made its ruling. The unfortunate phrase foisted upon the Council by the wording of an Act of Parliament, "infamous conduct in a professional respect," often created an unmerited sympathy with a person removed from the *Medical Register*, for his conduct might not appear at all infamous to the public. But if it were kept in mind that his removal meant little more than the omission of his name from a list of practitioners who preferred to be bound by the rule which he had preferred to break, the sympathy would not be so readily forthcoming.

In conclusion, Dr. Little spoke of the hostility to the medical profession in the House of Commons. The same hostility was not shown to the practitioners of law, perhaps because there were two hundred of them in the House, while there were only fourteen medical men. It was difficult to see why doctors should be so poorly represented, and he pleaded for a more general co-operation on the part of the profession in political problems. The students to whom he was speaking should from the first address themselves to questions of citizenship, especially as these affected, and were affected by, medicine, as well as to the practice of their profession.

## THE WORK OF THE MEDICAL STUDENT.

### ADDRESS BY PROFESSOR YEATES AT THE MIDDLESEX HOSPITAL.

THE opening of the ninety-second winter session took place on October 1st at Queen's Hall, Mr. S. G. Asher (chairman of the council of the Medical School) presiding, in the absence of H.R.H. Prince Arthur of Connaught, who was unable to be present owing to a prior engagement.

The introductory address was given by Dr. THOMAS YEATES (Courtauld professor of anatomy), whose subject was "*Ex nihilo nihil fit.*" A large number of people, he said, were work-shy, and they constituted the great class of men workers or idlers. They found their way into the medical schools. But, fortunately, there was another class of men—the workers—who carried on the work of the world, a much smaller class. Just as in a colony of bees one found workers and drones, so in a medical school there were the industrious and the lazy, the active and the passive, the useful and the useless. Work and its results in a medical school he considered under several headings. Work—the overcoming of resistance—appeared to be a universal and natural law. The medical student could not escape; he must earn his bread by the sweat of his brow. Likewise the medical teacher and research worker must work, no matter how intense the longing to avoid it. Happiness and contentment were rewards of work, and success—attainment of the goal aimed at—was a direct result. The idle student or teacher also got his de-erts—he was miserable.

### "Stuffing" the Student.

If work was essential for the successful study of medicine and for its research, the logical conclusion was that to serve up knowledge to a student in a pre-digested state must paralyse effort on the part of the student; mental dyspepsia resulted. Teaching (or rather cramming) in which the facts of the subject were presented to the student without any explanation how the knowledge had been gained, only attracted students devoid of ambition and whose only desire was to qualify and make a living. The process of stuffing the student was fatal to the evolution of his intellectual faculties, and teachers guilty of it were sinning against posterity. A medical man with inefficient training (in other words an incapable medical man) was a great danger to the community, and the hope was that the teacher producing such would sooner or later come under the care of one! The individual being taught must be an active and willing agent. To put this into practice: all medical study should be active, not passive. A student should attend regularly the courses prescribed, and try to gain a clear knowledge of the subject in hand. He should not simply aim at passing an examination on the minimum of knowledge. He came to a medical school to become an efficiently trained medical man, not to pass examinations. That work was essential, that it should be active not passive, that the struggle necessary to gain knowledge should be retained, and that the narrow road to knowledge must be trudged by all who wished to become educated—must be admitted by all. Hard, strenuous work on the part of the teacher and student was the method. The sooner those concerned admitted those contentions the better for the future of medicine, and the health, mental and physical, of the nations of the world. Work must be purposive and regular if definite results were to be gained. A definite object must be aimed at by the worker. In the laboratories of a school might be seen a group of youths looking quite exhausted. They were discussing a league football match, the winner of the Derby, or some entertainment to take place. They formed a large percentage of the community. They were workers that did not work—idlers, and of little interest. Then there were pale, pasty, anaemic, astigmatic, unshorn youths, worn out and exhausted by foolishly trying to memorize a book by heart, so that when an examiner—a greater fool than the student—touched the button, the record would be produced with painful accuracy. Such a student had surrendered his freedom and had become a slave to the word knowledge.

### The Art of Observation.

Then there was the keen, earnest, determined-looking youth, carefully modelling, freehand, the parts of a dissection; building up the parts to form a concrete solid model. Now he attempted to draw the original from nature, and, after an hour's work, deliberately destroyed his model and put the original away, and again attempted to model in freehand the specimen. He was aiming at establishing an image of the object—an accurate presentation—in his brain. A few days later he tried to model the same part without the original in front of him. He was slowly developing a solid, concrete, stereoscopic, x-ray image of the human body. In time that would become permanent, and, like his shadow, accompany him everywhere. In the wards, and, later, in his consulting room, it would be beside him, at once becoming visible at his command. He needed no textbook of the healthy man, as the image was ready to appear when he wished. The clinician trained him to gain a concrete stereoscopic picture of the structure of his patients so that the keen student could have, at his wish, transparent images of a healthy man, on the one hand, and beside that a transparent image of his patient on the other, for contrast. Diagnosis became a simple matter; that thoroughness of work led to the result aimed at—a full appreciation of the structure and working of healthy and diseased bodies. To see the organs, muscles, and so forth in their right relative positions to each other; to watch them working and undergoing chemical and physical changes—in fact, to observe life—was the aim of the student of medicine.

*Co-ordination of the Student's Training.*

Each stage in the education of a medical student (Professor Yeates went on) should interlock or dovetail with the previous and succeeding stages. Knowledge should be based on great general principles, and students should learn to reason from principles to the special study in hand. A student should not make the mistake of reasoning from the special to the general. He should refrain from depending on his memory. The medical man was a thinking animal, and the practice of medicine depended upon the application of great general principles, based upon observation, experience, and research. The sooner a student was set free from his teachers so as to allow experience to be his sole teacher the better for the growth of his real knowledge. Unfortunately, for evident reasons, it was extremely difficult, or almost impossible, to let a student have a direct experience in the treatment of diseases previous to qualification. It was evident, therefore, that study and work were essential after medical birth, and this should continue throughout life. A medical man ceasing to gain experience from his work should consider whether the community would not be better served by his giving up practice. Lack of co-ordination in the various stages of the student's training was in part due to the fact that the subjects were taught by men who had little experience of the work of later years. That referred to every stage of the student's career, not excepting the final year, for how many clinical teachers in hospitals had any experience of general practice? How many of them were acquainted with the early phenomena of disease by first-hand experience? Were the clinicians not training men to perform duties as general practitioners, duties of which many were more or less ignorant? Would it be too much to demand that every teacher in a medical school should start life as a general practitioner? Should a general practitioner, an ordinary doctor, not be a member of the staff of every teaching hospital? Should ordinary catarrhal conditions in children be passed by as of little account, whilst rare and incurable diseases, such as acromegaly, were carefully and minutely studied? Was it not better for the future of national health that a student should be thoroughly taught how to recognize and treat a suppurating finger or a common cold, or should a prospective medical man have no knowledge of those mild ailments? Should much of his time be taken up watching, from a distance, obscure and difficult operations which would only be undertaken by highly trained specialists? The medical student should, as an undergraduate, work to get a sound knowledge of the very earliest signs of disease, in addition to studying the pronounced cases which were so common in all hospitals. No attempt should be made at specialism until after graduation. To become a specialist appeared to be easy, but gaining the experience and knowledge necessary to be a great doctor was only possible to a few men. Students might believe that on becoming qualified all their troubles would cease, but work was now even more important, for, being freed from the influence of the medical school and the financial assistance of his home, he found life hard and difficult. Patients wisely avoided him; they did not want to be experimented on. He had thus little chance of studying disease in private. He had his chance now, if he would only take it. Let him become a keen student of disease. He should practically live in the hospitals. He could not afford to wait for cases at home. A stray case might call on him—a non-paying patient of a colleague—let him study that case with great care, for there was very little chance of his seeing it a second time!

A young practitioner should look forward to a hard life, with little remuneration. The practical doctor had greater opportunities to carry on investigations bearing directly on the treatment of disease than the laboratory worker. Large unexplored fields were open to all workers, and if the harvest was to be gathered there must be no strikers, no idlers, no dole-receivers in the profession. An eight-hour day was an absurdity.

*The Work of the Teacher.*

Time would not permit (said Professor Yeates in conclusion) the consideration of the work of the teacher, but

what had already been stated about the student's work applied equally to that of his teacher. Any observer, no matter how casual or careless his observations, could group teachers into two classes. The first type of teacher was the man who professed to be a teacher until he was appointed to be one. On appointment he treated his students like the Duke of Plaza Torro—"He leads his regiment from behind—he finds it less exciting." He now looked down on teaching as a profession, and retired to the privacy of his room to carry out his life-work—a work, no doubt, of the greatest importance to the welfare of the world. The second type of teacher was the one who attempted to teach, and, as a consequence, was forced to make a continual series of original investigations. It was that type of man that was needed to perform the work of a medical school. If *ex nihilo nihil fit* was true, work was the best and only means of acquiring the knowledge necessary to gain the mastery over disease, and the hope was expressed that, as a direct result of that knowledge, there would be a spread of health, industry, and contentment among the peoples and nations of the world.

The DEAN (Mr. Eric Pearce Gould) presented the report for the past year, and in the course of doing so said that the extension of medical knowledge was, and must remain, dependent upon the labours of duly qualified workers with a zest for research; but the supply of such men would fail, and their zeal be quenched, unless funds were available for their training and support, and for the equipment and upkeep of laboratories. Gifts like those mentioned in the report encouraged the belief that that statement was to-day almost a platitude. To parody the well known slogan, "You provide the money and they (the men of science) will do the rest."

The prizes were presented by the ARCHBISHOP OF CANTERBURY, who, after the presentation, said that as he listened to the Dean's report there arose before him visions of those who had passed away. Three of those mentioned in the report were personal friends of his: the late Sir Richard Douglas Powell, whose grace and courtesy were an asset of enormous value to all his friends; Sir Henry Morris, whose vigorous personality was infectious, and who made one feel keen to do the things he was keen about himself; and Mr. Stephen Paget, whose wisdom and wit were such as to endear him, not only to medical men, but to people outside the medical profession. He wished success and God-speed to the splendid effort which was being made on behalf of the Middlesex Hospital to overcome difficulties which to most people would seem insurmountable, but which were being steadily overcome.

**ST. BARTHOLOMEW'S HOSPITAL.****OLD STUDENTS' DINNER.**

In accordance with long-standing custom, the new winter session at St. Bartholomew's Hospital began without formal ceremony, other than the annual old students' dinner, which was held on the evening of October 1st in the Great Hall of the hospital. The chairman, Mr. W. T. Holmes Spicer, F.R.C.S., consulting ophthalmic surgeon, was supported by Lord Stanmore, treasurer of the hospital, Sir Anthony Bowlby, Sir Archibald Garrod, Sir William Beveridge, Vice-Chancellor of the University of London, Sir Holburt Waring, Dr. H. Morley Fletcher, and Sir Matthew Fell, Director-General, A.M.S.; the City of London was represented by Sir Charles Wakefield, formerly Lord Mayor, and Sir Wilfrid Atlay, formerly chairman of the Stock Exchange Committee.

The chairman, in proposing prosperity to St. Bartholomew's Hospital and Medical College, touched upon some of the outstanding events of the past year. One of the most important of these was the completion of the Queen Mary block of buildings for the housing of the nursing staff. Another was the decision to provide an operating theatre block in connexion with the new surgical block, which would enable in-patients to be taken straight to bed after operations without passing through the open Square. A third matter of great importance which

concerned the welfare of the whole community was the decision to provide a block for paying patients. Mr. Holmes Spicer believed that in the future all operations and a large part of the medical treatment of non-charitable patients would be carried out in the paying departments of the great hospitals, because no one, even the most wealthy, would be able to command the best treatment elsewhere. In any scheme of hospital reconstruction the needs of paying patients must be regarded. Turning to the work of the medical college, he said that the staff were to be congratulated on a very successful year's work; 120 students had obtained their qualifications to practise, and new students to about the same number had joined during the year. In its endeavour to keep the school in the front rank in all matters concerning education and research, a whole-time resident physician-accoucheur, Dr. Wilfred Shaw, had been appointed, and a laboratory in memory of the late Dr. Herbert Williamson had been attached to this department. A new and far-reaching scheme for the transfer of all the college buildings to the other side of Giltspur Street was already in the air, but a very large sum of money, perhaps £140,000, would be needed to bring this about. Such a school with the finest equipment in the country would attract more and more of the best students; for unless it gave the best, and something better than the best, something that anticipated the needs of future generations, Bart's would not keep its great place in the world.

Lord Stanmore, in responding to the toast, added to what the chairman had said about the completion of the second wing of the nurses' home; the getting out of plans for new surgical and operation blocks, with accommodation for 250 patients, and a paying block; and the unveiling of the war memorial on July 8th last by the Prince of Wales, President of the Hospital. In regard to finance, the hospital had been fortunate in securing a number of legacies during the past few years, thus enabling it to pay its way and to put by something substantial for emergencies. He recognized that one of the real needs of the future was a residential college for students.

The health of the guests was proposed by Sir Percival Horton-Smith Hartley, who welcomed these distinguished pilgrims to St. Bartholomew's, and not least old friends like Sir Archibald Garrod and Sir Matthew Fell, whose distinctions elsewhere reflected honour on their school. Sir William Beveridge, in replying, had to confess himself a Vice-Chancellor of London University but not a medical man—a thing that scarcely ever happened, even though some of the Senators ate an apple a day! London, he said, although its schools were known far and wide, scarcely knew its own university. The problem was whether besides its constituent colleges there should be anything in the nature of a real central university for the metropolis. This question, whether London University should have an independent life as a whole, arose on many issues.

The chairman's health was proposed with warmth and wit by his old friend and fellow student Dr. Owen Lankester, whose praises of "Tom Spicer" were received with cheers. A most successful dinner ended with congratulations to the organizers, Sir Charles Gordon-Watson and Mr. Reginald Vick, who each, like the chairman, made very brief acknowledgement.

### ST. MARY'S HOSPITAL.

#### ANNUAL DINNER.

THE annual dinner of St. Mary's Hospital Medical School took place at the Connaught Rooms on Monday, October 4th, when Dr. G. W. H. French was in the chair. There was a large attendance.

The customary loyal toasts having been honoured the chairman proposed the toast of prosperity to St. Mary's Hospital and Medical School. He said that the outstanding event of the year was the appeal for the proposed scheme of new buildings, which would provide two modern operating theatres, many more beds, and increased accommodation for the nursing staff. The existing theatres were not up to date, and there was also a great need for additional beds, many of which it was proposed to use for casualty

cases in view of the alarming increase in the number of street accidents. When the hospital got its new theatres and additional beds there need be no fear about the future; the hospital and school were bound to increase their present high reputation in the world. In referring to the deaths among members of the staff of the hospital during the past year, the chairman mentioned in particular the names of Mr. Herbert Page, Mr. Clayton-Greene, and Dr. R. H. Cole. In looking through the annual report of the school he was struck with the extraordinarily high percentage of passes of men who had worked at St. Mary's Hospital for the Primary Fellowship examination of the Royal College of Surgeons in December last; it was no less than 55 per cent.

In responding to the toast, Mr. A. R. Prideaux, chairman of the hospital board, said that the King Edward's Hospital Fund for London thoroughly approved the proposed additions to the hospital and offered a contribution of £4,000 on condition that the work was commenced before December 31st, and providing that the sum of £20,000 was raised before that date towards the expense of the scheme. He was glad to say that this sum was raised within five weeks of the opening of the appeal which was carried out by the administrative staff of the hospital, and the extra cost entailed did not exceed £150. Negotiations had been opened for obtaining additional land adjoining the hospital, and he hoped they would be successful. Dr. C. M. Wilson, dean of the medical school, also replied and gave interesting figures with regard to the growth of the school. The toast of the chairman, proposed by Sir William Willcox, K.C.I.E., was received with musical honours, and was duly acknowledged by Dr. French.

### WESTMINSTER HOSPITAL.

THE opening ceremony of the new session at the Westminster Hospital Medical School took place on October 1st in the Board Room, under the chairmanship of Mr. Austin Taylor. Sir Archibald Garrod's introductory address on the science of clinical medicine is published in full in this issue (p. 621). The Dean of the Medical School, Dr. A. S. Woodwark, in reporting on the work of the past session, said that the number in attendance had surpassed that of any year since 1900, and that the standard of work attained and the successes won were most satisfactory.

The annual old students' dinner was held on the same evening at the Royal Adelaide Gallery, under the chairmanship of Mr. William Turner, senior surgeon to the hospital. There was a large attendance, and, as usual, formality was replaced to a large extent by the spirit of a happy family gathering. The speeches were short and to the point. The toast of "The School" was proposed by the chairman, and in reply Dr. Woodwark gave a brief account of the favourable prospects, including the increasing recognition accorded to the school by the War Office for the post-graduate training of medical officers. The toast of the "Past and Present Students" was also proposed by the chairman, and, in reply, Dr. H. R. Coombes, in reminiscent vein, referred discreetly to adventures of the past, and Mr. R. Greene expressed the aspirations of the present students. The toast of "The Chairman" was proposed by Dr. G. Brittan Gill in an appreciative speech. A good musical programme added to the enjoyment of the evening.

### CHARING CROSS HOSPITAL.

FIELD-MARSHAL SIR WILLIAM ROBERTSON, after presenting, on October 6th, the medals, prizes, and certificates at the Charing Cross Hospital Medical School, reminded the students that, though during the last half-century or so science had made great strides, there were many defects in the field of medicine and in the field of surgery which needed remedying. Some of them were sufficiently grave to leave ample scope for ambition. Exactly how they should be tackled scientifically it would be presumptuous for him to say, but they existed, and they would not be solved except by dint of much hard work and research. The responsibility for their solution rested mainly upon

the younger generation. Coming down to what he might call the ordinary day's work of a member of the medical profession, he would suggest to the students that, although good technical skill and good theoretical knowledge were essential preliminaries to success, they were not of themselves sufficient. They needed to be reinforced by qualifications of more or less the same kind as were common to other professions and in business. The medical man must train himself to come to decisions and act promptly and not be afraid to take a certain amount of risk. It was necessary for him to have a good sound knowledge of human nature and to possess a high standard of character. Science had gone far, and with its progress there had been a great spreading of education among the public in general. The patient to-day was quite a different person from the patient of, say, fifty years ago. He was not to be fobbed off by a mysterious shake of the head or by some high-sounding medical phrase. There was a tendency at the present time to call in the specialist in substitution for the general practitioner. In some cases the services of the specialist were necessary; but it was not infrequently stated that nowadays the supplementing of the general practitioner by the specialist was being carried to limits which could not always be justified. If that was so, the more closely the training of the medical student could be brought into line with the requirements of the general practitioner the better it would be.

## Union of South Africa.

[FROM OUR CORRESPONDENT IN JOHANNESBURG.]

### THE SOUTH AFRICAN INSTITUTE FOR MEDICAL RESEARCH.

FOLLOWING the announcement of the resignation owing to ill health of Dr. Wilfred Watkins-Pitchford from the Directorship of the South African Institute for Medical Research, Johannesburg, comes the announcement of the appointment of Sir Spencer Lister to that post. Both men have rendered signal service to South Africa by assisting the development of medical research. In 1911 the Witwatersrand Native Labour Association launched the scheme for establishing an institution to be devoted to the purposes of medical research, and a joint committee, representing the Government and the association, was formed to carry out the project. This committee invited Sir Almroth Wright to visit Johannesburg and investigate the problem of lobar pneumonia, which was then a formidable scourge to the natives in the mines. Wright introduced the method of protecting against pneumonia by means of inoculation with a pneumococcus vaccine. This method was later considerably elaborated by Spencer Lister after he had joined the staff of the institute. His researches led to the devising of the immunizing vaccine with which the mine natives have been inoculated as a routine procedure during the last ten years. In 1912, on the recommendation of Sir Almroth Wright and General Smuts, Dr. Watkins-Pitchford was appointed first director of the institute. Since that date the work undertaken there has increased to such an extent that in 1923 it was found necessary to enlarge the building very considerably. The growth in the routine work has been very great: in 1919 the number of specimens examined was 17,000, but in 1925 the total had increased to 52,800. In addition to this diagnostic service the institute has for several years past issued considerably more than one million doses of various vaccines and serums annually. The work of the research division, which was inaugurated by Sir Almroth Wright, has expanded with the increasing accommodation and funds, and has earned for the institute a wide reputation. Besides lobar pneumonia the subjects which have been fruitfully investigated include miner's phthisis, schistosomiasis, helminthiasis, dysentery, scurvy, and cerebro-spinal meningitis. It is a striking fact that the annual death rate from disease among the 200,000 natives employed on the Rand mines has fallen from 28.3 per 1,000 in 1911 to 9.3 in 1925.

### Farewell Lunch to Dr. Watkins-Pitchford.

The many farewell functions accorded to Dr. Watkins-Pitchford included a luncheon by the Mayor of Johannes-

burg. In replying to the toast of his health, he thanked the mayor for the opportunity of bidding farewell to some of the leading citizens of the town, and said it was a grave crisis in the life of a worker when he was called upon to relinquish his labour and to put away his tools finally. The most noxious disease with which an intelligent man could be afflicted was chronic unemployment. In their vigorous and restless community, containing numerous representatives of all the principal races and creeds of the world, there were but few ideals common to all, perhaps only one—the welfare of humanity. The South African Institute for Medical Research had been established by the gold mining industry of the Transvaal as an expression of this common ideal of the people. The work of this institution was not performed for the monetary gain of any individuals, nor for the advantage of any section of society, but was carried on against the common enemies of mankind—disease and death. This had been symbolically expressed in the bronze finial which surmounts the dome of the building. Dr. Watkins-Pitchford believed the time was not far distant when the maintenance of medical research in our midst would be raised above the chances and changes of party politics and the fluctuations of local industry. When the conscience of the people had been fully awakened the future of the work would be secured.

### Sir Spencer Lister.

Sir Frederick Spencer Lister, who has been appointed Director of the South African Institute for Medical Research, received his medical education at St. Bartholomew's Hospital. After coming to South Africa he was for some years assistant medical officer at the Premier Diamond Mine near Pretoria. From 1912 until 1917 he was medical officer of the Durban-Roodepoort Deep and Bantjes Mines on the West Rand. At first temporarily attached to the South African Institute for Medical Research, his services having been lent by the mines, he joined the institute permanently in 1917, and was appointed research bacteriologist. Sir Spencer is best known in the scientific world in connexion with his researches on pneumonia prevention amongst the mine native employees on the Rand by means of prophylactic inoculation. This work extended over many years, but the main portion of it was finished in 1918. Since then he has tackled several bacteriological problems, more especially those of influenza and the filterable viruses. He has been chairman of the Witwatersrand Branch of the British Medical Association, and also of the Associated Scientific and Technical Societies of South Africa. In 1921 he received the South African medal and grant of the Association for the Advancement of Science. He recently returned to South Africa after a six months' tour of research institutions in Europe and America.

### UNIVERSITY OF THE WITWATERSRAND.

Sir Spencer Lister has been appointed honorary professor of pathology in succession to Dr. W. Watkins-Pitchford. The following candidates have been successful in Part I of the examination for the diploma in public health: J. M. B. de Wet, G. D. Laing, D. Ordman, F. H. Welsh. Part II of the examination will be held in March, 1927. Regulations are being drafted for two new diplomas in the Faculty of Medicine: D.P.M. and D.T.M. The course for the diploma in psychological medicine will commence next year. It will extend over twelve months, six of which are to be spent in an appointment as resident medical officer in a mental hospital approved by the university. The examination will be divided into two parts: Part I to include psychology and the anatomy and physiology of the nervous system; Part II pathology, neurology, and psychiatry. The need for a post-graduate course in tropical medicine in this country has long been felt, but there have been many practical difficulties in the past. It now appears that the proposed diploma course will be made available in the reasonably near future. The Otto Beit Chair of Physiology has become vacant owing to the resignation of Professor E. H. Cluver, who leaves the university to take up the appointment of assistant health officer for the Union.

## THE LATE DR. JAMES ERLANK.

The sudden death of Dr. James Erlank, at the age of 38, has caused very deep regret amongst his colleagues in Johannesburg. One of the younger school of surgeons, he was recognized as a coming man in the profession on the Rand. He had for several years been treasurer to the Witwatersrand Branch of the British Medical Association, and last March was appointed secretary to the South African Committee, in which capacity he did a great deal of work in connexion with the recent visit to South Africa of Dr. Cox. Dr. Erlank graduated M.B., Ch.B. Edin. in 1910, and obtained the diplomas D.P.H. Lond. in 1914 and F.R.C.S.E. in 1919. He held the post of senior house-surgeon at the Cancer Hospital, Fulham, London. He went on active service with the British Red Cross in 1914, and was appointed an honorary captain in the R.A.M.C. He was attached to the Meerut Stationary Hospital, and subsequently was surgeon at the Duchess of Westminster's Hospital in France. He was mentioned in dispatches for meritorious war service. He was a member of the Rand Club and also of the Wanderers Club, and was held in high esteem for his surgical skill and his engaging personality.

## England and Wales.

## SMALL-POX IN WILLEDSEN.

On September 29th Dr. G. F. Buchan, medical officer of health for Willesden, was called to see two cases (man and wife) by the medical practitioner in attendance. He found the man to be suffering from small-pox in a modified form and the woman from haemorrhagic small-pox. The cases were removed to the Willesden Small-pox Hospital the same day. The clinical features of these cases are described by Dr. Troup, the medical superintendent, as follows:

*Husband, aged 43 years.*—Vaccinated in infancy, revaccinated in or about 1900.

*Condition on Admission to Hospital.*—There were a few dry scabs on the hands, wrists, and feet, but the large majority of the lesions had completely healed, leaving no scar. It was not possible to differentiate accurately the site of all the pustules, but as far as could be ascertained these were as follows: Three on face, a few on scalp, three on shoulders and neck, three on abdomen, two on flanks, four on arms, four on hands, one on right thigh, two on feet (dorsal surface). The patient walked into the hospital, and had nothing to complain of. On October 2nd all scabs had completely disappeared, leaving a small scar in some instances.

*Wife, aged 44 years.*—Vaccinated in infancy.

*Condition on Admission to Hospital.*—Temperature 97° F., pulse 64. A haemorrhagic rash was present on the trunk, arms, fore-arms, thighs, and legs, being most marked in the axillae, groins, and wrists. The haemorrhages took the form of petechiae and ecchymoses, the latter form being chiefly present in the axillae and groins. A diffuse erythema was present on the trunk and extremities, most marked on the shoulders posteriorly. The face was slightly bloated, and there were no haemorrhages present in this region. The patient had a characteristic fœtor, and was quite conscious. The conjunctivae were injected only. The tongue was thickly furred and the mouth dry. Metrorrhagia was present. There were excruciating pains in the back, and the patient was in great distress. There were no papules, vesicles, or pustules present. A hypodermic of morphine was given, and the patient remained quiet for about five hours. She was seen again at 11 p.m. The haemorrhages on the trunk and extremities had increased in size and number. The face and lips were a livid hue, and the former was more markedly bloated. The pulse could not be felt. The patient was very restless and in a semi-conscious condition; she died at 11.45 p.m.

Inquiries into the history showed that the patients had arrived in London from Paris on September 5th and had gone to a west central hotel, from which they moved to a West End hotel on September 7th. On September 8th the husband became ill with pains in the back, headache, severe prostration, and a temperature of 105° F. This was followed two days later by a rash which appeared first on the scalp and face and subsequently on the arms and legs as described above. On September 19th both patients were moved to a nursing home in Brondesbury, Kilburn. On September 24th the wife became ill with severe pains in the back, followed by headache, vomiting, extreme restlessness, and sleeplessness. On September 26th an erythematous rash appeared in the axillae and groins, subsequently becoming punctate, and on September 29th it was as above described.

Both patients were in Paris during the last fortnight in

August, and apparently it was during the last week of that month that the husband was infected. It is reported that there is small-pox in Paris. The husband had been vaccinated and revaccinated and took the disease in a modified form. He apparently infected his wife, who developed small-pox of the virulent type; she had not been vaccinated since infancy.

The medical officers of health of surrounding districts in which the patients had resided or from which they had been visited were communicated with. Contacts were traced as far as possible and vaccination advised, and the necessary disinfection was carried out. At the West End hotel the medical officer of health of the metropolitan borough concerned, Dr. Charles Porter, ascertained that one of the staff had been ill for about thirty-six hours with suspicious symptoms, and that another of the staff was ill in Lambeth. Both of these cases have subsequently been notified as small-pox. The usual period of two days which elapses between the onset of the disease and the appearance of the rash gives an opportunity for preventive measures to be taken, as it enables the patients, who are not infectious during this period, to be isolated. All medical practitioners in Willesden have been notified of the circumstances of the occurrence of the disease and are actively co-operating with Dr. Buchan to prevent, as far as may be, any spread. Should no further cases arise Willesden will be free from danger of spread from the patients imported into the district probably about October 13th and certainly by October 20th.

It is reported in the press that a middle-aged woman has died in South Shields from small-pox. The medical officer states that four fresh cases occurred last week and that the disease is taking a virulent form.

## LIVERPOOL ROYAL INFIRMARY: NEW MATERNITY DEPARTMENT.

A new maternity department, the gift of Mr. Domingo de Larrinaga, a Liverpool shipowner, was formally opened by the Lady Mayoress, Mrs. E. W. Hope, on September 28th. Sir James Barr, president of the Royal Infirmary, said that such a department was an innovation so far as Liverpool was concerned, but it was long overdue, for there was a general impression throughout the country that midwifery was not as well cared for in the matter of medical education as was medicine and surgery. There was a great need for such training, not only for the future medical students, but also for obstetric nurses. In this country 3,000 women died every year in childbirth, and sepsis in some form or another claimed 1,000. Professor Blair Bell, in seconding a vote of thanks to the generous donor, said he had always felt that a gynaecological clinic was incomplete unless a properly equipped obstetric department was also instituted, for diseases of women and the accidents of childbirth were inseparably interwoven. From a teaching point of view he rejoiced that the medical students would now have the opportunity of acquiring a sound practical knowledge of obstetrics in a general hospital and gain clinical experience, under signal advantages, of the complications that might arise in childbirth. Further, the nurses trained at the Royal Infirmary would now be able to gain their obstetric experience necessary for the C.M.B. certificate. An extension of the x-ray department has been made for the express purpose of obstetric cases requiring such examination, and suitable delivery theatres have been added.

## LIVERPOOL MATERNITY HOSPITAL.

The first section of the new building of the Liverpool Maternity Hospital was informally opened for the reception of patients on April 26th. The formal opening took place on September 29th, when Miss Hartley, ex-mayor of Southport and daughter of the late benefactor, who gave £50,000 to the building fund, unlocked the door. She expressed the fervent hope that the hospital would in turn open up a roadway for a healthier race, on whom depended the happiness and prosperity of the country. Sir George Newman gave an interesting address dealing with the importance of maternity and child welfare, which lay at the very root of national health. Incidentally he said that in the year between 25,000 and 30,000 children were stillborn, and that of those born alive 50,000 would not live

to see their first anniversary. In this new hospital he felt sure that every endeavour would be made to reduce these distressing figures. He rejoiced to see that the Government and the General Medical Council had made arrangements for perfecting the medical curriculum and imposing upon every medical student a new and enlarged kind of training in obstetrics. Dame Mary Scharlieb touched on the history of the Liverpool institutions, of which the present new building was the result. She made an appeal to the citizens of Liverpool, which had been a pioneer in everything that was good and noble, to support and complete this beneficent undertaking. At present fifty-four patients can be accommodated. In the main section, in which are also the nurseries, there are four eight-bed wards and eight single beds. The extension contains two five-bed wards and two double-bed wards. When the hospital is completed 100 mothers will be provided for. There is a well equipped pre-natal out-patient department, and an infant clinic in which special attention is given to infant dietetics. The labour wards, operating theatres, and recovery rooms represent the latest improvements in obstetric science. There is a roof garden readily accessible by a bed lift.

#### NEW SCHOOL CLINIC AT BIRMINGHAM.

A second school clinic in Birmingham was opened on September 30th to deal with a limited sphere of minor operations, including those in connexion with defects of the teeth, eyes, tonsils, adenoids, and ear discharges. The departments in the building are conveniently arranged and very well equipped. In addition to a central assembly room there is accommodation for a staff of two medical practitioners and three dentists, including consulting rooms and dental operating rooms. For the treatment of muscular defects and deformities a remedial exercises department has been established. The scabies block contains special baths and sterilizing plants for dealing with skin diseases. One room is provided for the treatment of minor ailments, and another for testing vision. Good accommodation is available for stores, heating appliances, and other administrative essentials. At the opening ceremony Sir Humphry Rolleston gave a comprehensive survey of the functions of a school clinic, with special reference to its preventive aspect. He commended the pioneer work of the Birmingham Education Committee in arranging for the treatment and supervision of rheumatic, cardiac, and choreic children, and emphasized the importance of preventive treatment in infancy and childhood. He mentioned that the total gross cost of the school medical services in 1923-24 was £1,220,268, or only about one-fiftieth of the total amount spent on public elementary education; this was a very small premium for rendering education a useful asset and for improving the physical and financial health of the nation.

#### EXTENSIONS AT STOCKTON AND THORNABY HOSPITAL.

H.R.H. Princess Mary Viscountess Lascelles opened on September 23rd the new extensions of the Stockton and Thornaby Hospital, which serves the two Teesside boroughs of Stockton and Thornaby and the surrounding district. The original hospital was opened in 1862 with accommodation for six patients; fourteen years later it was transferred to its present site, and then provided for 31 in-patients. In 1890 a new wing was added, which practically doubled the accommodation, and seven years later, with the erection of another wing and the addition of a story to the central block, the total number of beds rose to 72. The demand for its services is illustrated by a waiting list of about 200, and it is hoped that the present extensions, which were begun two years ago, and increased the number of beds to 133, will substantially reduce the period of delay before admission. The new buildings include a nursing home, additional wards for children and adults, an out-patients' department and dispensary, an orthopaedic and electro-therapeutic department, including provision for heliotherapy, a skin clinic, improved operating facilities, an additional electric lift, new quarters for the resident medical officers, and an enlarged and remodelled kitchen. During the year which ended on June 30th, 1,535 in-patients were admitted and 1,083 operations performed. Sir Frank Brown, the president of the hospital, welcoming Her Royal Highness,

described the success which had attended the efforts of the mayors of the two boroughs to raise the necessary funds for the extensions, as the result of which all the expenses had been met. It was stated also that for some years past the workmen of the two boroughs had contributed by their subscriptions no less than four-fifths of the cost of maintenance of the hospital, and that for the last forty-three years no financial year had closed with the hospital in debt.

## Scotland.

#### THE GENERAL BOARD OF CONTROL FOR SCOTLAND.

THE annual report by the Commissioners of the General Board of Control for Scotland includes a review of fifteen years' lunacy and mental deficiency statistics—from 1910 to 1924. The figures reveal an apparent decrease in lunacy, as the proportion of registered lunatics to each 100,000 of the population was 390 before the war, 374 during the war years, and 369 since the war. The total number of persons suffering from mental disorders is, however, really increasing, when the operations of the Mental Deficiency Act are considered over the same period of fifteen years. During the first period the operation of the Mental Deficiency and Lunacy (Scotland) Act of 1913 had not taken effect. In the second quinquennium—that is, the war period—the Mental Deficiency Act was in operation, and the number of mentally defective persons on the register steadily increased. This increase has gone on during the third quinquennium. From 1910 to 1914 the average annual number of mentally defective pupils in training at institutions was 546, while from 1915 to 1919 the average number of mentally defective persons certified under the Act was 1,236. By the end of 1924 the numbers had increased to 2,308. These statistical data of mental deficiency must be added to those of mental disorder to give a proper conception of the incidence of mental affections in the community. In the first five years under review many mental defectives who could not be certified under the Lunacy Acts were left uncared for and drifted into habits often tending to crime. The certification, under the Mental Deficiency Act, of mental defectives who had formerly been sent to asylums more than accounts for the diminished numbers of cases of lunacy now entering asylums.

#### Early Treatment of Mental Disorders.

The report deals with the early treatment of mental disorders, which has engaged the attention of the Board for many years. Voluntary admission is stated to be freely and increasingly resorted to by private patients entering royal and district asylums. The parish council of Glasgow inaugurated hospital wards for the treatment of incipient forms of mental disease in 1890, and the success of these special wards was so marked that two special wards, each containing twenty-five beds, were set aside as mental and observation wards in the new hospital opened in Duke Street. This example was followed by the parish councils of Govan, Paisley, and Dundee, and in 1924 observation wards accommodating eighty patients had been set aside for the treatment of cases of incipient, temporary, and unconfirmed mental disorders in the general hospital at Stobhill. The report states that in consequence of the institution of these observation wards the erection of a third asylum for the Glasgow district has been avoided, and that the advantages gained by hundreds of patients who, as the result of treatment in observation wards, have not required to enter asylums is immense. Into these observation wards, which have in all 160 beds, were admitted in the course of the year under review 1,176 patients, of whom 611 were discharged, while 383, or less than 33 per cent., required to be certified and sent to asylums.

#### Forms of Treatment.

Sanatoriums and reception houses for the treatment of tuberculous patients were erected in the Glasgow asylums over a quarter of a century ago. So much success has attended them that similar sanatoriums or spacious verandahs for open-air treatment have been erected in all the institutions under the Board. The necessity for these

sanatoriums is evident from the fact that tuberculous affections were found to be four times more prevalent among asylum patients than among patients in general hospitals. The extensive use of outdoor and sanatorium treatment for all classes of patients has brought the number of tuberculous cases down to the level obtaining in ordinary hospitals. Many other patients in frail physical health have been placed in these special buildings, and the treatment found beneficial in tuberculous affections has proved beneficial in other cases also. The advantages of occupational therapy are fully recognized by the Board. Farms are attached to twenty-two of the district asylums. The Board, in encouraging the acquisition of farm and garden ground for the therapeutic occupation of patients, has suggested that all institutions provided for mental affections should have a minimum of one acre of ground for each male patient. Many interests in farming and occupations in gardening can also be found for women. Other methods of occupational therapy have proved of benefit in the case of patients whose mental state is such that they cannot be employed on farm or garden work in a regular manner. The Board commends the appointment, in many institutions, of consulting dentists who have at their disposal adequately appointed dental rooms. The value of ultra-violet light treatment has been experienced in a number of institutions, and it is suggested that in the care of mental affections of a temporary and curable nature the treatment of nervous and mental affections by light, electrical means, and hydro-therapy might be carried out in dispensaries and clinics.

#### *Encephalitis Lethargica.*

In the Board's last report reference was made to the fact of lethargic encephalitis in producing mental affections, and it was suggested that it would be desirable to group such cases, if possible, in one institution. By an arrangement with the Board of Health, public authorities throughout Scotland have now been enabled to send cases of encephalitis lethargica to Stobhill General Hospital.

#### *Lunacy Statistics.*

On January 1st, 1926, there were in Scotland 18,537 insane persons, exclusive of those maintained at home by their natural guardians. The number at January 1st, 1925, was 18,398, so that an increase of 139 had taken place during the past year. The total number of patients admitted to establishments during 1925 under a sheriff's order was 3,180, or 52 less than in the previous year. Of these, 481 were private patients, or 44 less than in the previous year, while the number of pauper patients was 2,699, or 8 less than in the preceding year. Voluntary patients, it is pointed out, enter asylums voluntarily for treatment of mental disorder, with the sanction of the Board granted on a simple application by the patient. They cannot be detained for more than three days after giving notice of their intention or desire to leave, and they are not certified as insane nor registered as lunatics, although a record is made of their names and other particulars regarding them. The whole number of such persons admitted into asylums in 1925 was 482, and the number resident on January 1st, 1926, was 597. During 1925 the number of private patients discharged recovered was 201, while 951 pauper patients were discharged recovered. The number of private patients who died in establishments during 1925 was 243, while the number of pauper patients dying was 1,183. The death rate for patients in establishments was 8.6 per cent. of the average number resident for the year, as compared with 9.6 for the previous year. The whole number of escapes during 1925 was 144. Of these, 57 were brought back within twenty-four hours, 39 within a week, and 21 after a week. There were still 27 absent on the expiry of twenty-eight days from the date of escape. Of these, 2 were removed from the asylum registers as recovered, 15 as relieved, and 8 as not improved; 2 died.

#### *Working of the Mental Deficiency Act.*

Since the passing of the Mental Deficiency (Scotland) Act in 1913 the Board has made every effort to carry out its provisions, although difficulties, largely of an economic nature, have been encountered. The Treasury instructions of 1921 limit the numbers of defectives in

institutions who would be entitled to participate in the imperial grant to 1,477. The privileges were, however, extended by a further sum of £5,000 towards the cost of providing for 200 additional mentally defective persons. During the coming year it is expected to utilize this for 100 beds in the institution at Birkwood (belonging to the Lanark District Board of Control), for 50 beds in the Broadfield institution (belonging to the Paisley District Board), and for 50 beds in the institution belonging to the Edinburgh District Board at Gogarburn. An application of the Edinburgh District Board of Control for authority to provide institutional accommodation for 500 defectives has received the sanction of the Treasury. Various other smaller institutions have also obtained Treasury grants. In addition to these, 1,009 rate-aided mentally defective persons are provided for in private dwellings, and there are fourteen institutions with accommodation for 1,790 certified defectives. The urgent needs for mental defectives are stated to be accommodation, educational facilities for the young, and extended means for the care and supervision of persons over 16 years of age. The returns show that there are 12,969 mental defectives throughout Scotland, of whom 1,709 are certified under the Lunacy Acts and placed in asylums. The total number returned by education authorities—who are responsible for defectives between the ages of 5 and 16—as capable of receiving education was 5,145. The number of mental defectives reported by parish councils to be incapable of education was 742. The parish council is the authority which deals with all mental defectives over 16 years of age, and the number of these returned by the parish councils was 3,384.

#### *ABERDEEN CITY HOSPITAL EXTENSION.*

The public health committee of Aberdeen Town Council has approved a report proposing extensions and additions to the Aberdeen City Hospital. It makes provision for additions to the nurses' home at a cost of £27,000 for one sixty-bed ward and two forty-bed wards at a cost of £22,500, and for a venereal disease ward and centre at a cost of £11,000. The total cost of the scheme is estimated at £60,500, of which, deducting Government grants, £40,150 is to be borne by the town council.

#### *INCREASED INSURANCE BENEFITS IN SCOTLAND.*

The report presented to the annual meeting of the Scottish members of the National Amalgamated Approved Society, held in Edinburgh, when Mr. G. Tilley, F.F.I., was in the chair, showed that during the year 1925 the sum of £135,086 had been paid to Scottish members of the society in respect of sickness, disablement, and maternity benefit. This was an increase of £3,852 over that of the previous year. The surplus disclosed by the annual valuation would, as the chairman stated, enable the committee of management to announce an increase of benefits during the next five years. This would include additional treatment benefits—dental, optical, and convalescent home—and the provision of medical and surgical appliances, nursing, and contributions in respect of members receiving in-patient treatment at hospitals. During the year 1925 free legal assistance had been given by the society in cases of accident and industrial disease, and compensation had been secured for 29,157 members, involving various sums up to, in one case, £1,227. The total funds now invested on behalf of insurance members of the society amounted to £771,640.

#### *PRIVATE PATIENTS IN COUNTY CLARE HOSPITALS.*

A CONTROVERSY as to whether, and under what conditions, doctors in charge of public hospitals maintained out of the rates may charge fees to paying patients led to a sworn inquiry at Raheen (Scariff) District Hospital, held by Dr. A. D. Clinch, medical inspector of the Local Government Department. In Clare, patients admitted to such hospitals must pay for their maintenance if their valuation exceeds a certain figure. In addition, they must, according

to the contention of the doctors, pay fees for the treatment they receive. The argument of the medical profession is that the admission of such patients to public hospitals deprives the doctors in charge, and also deprives private practitioners, of the chance of private practice. On the other hand, members of the Clare Board of Health hold that the doctors are paid salaries for the treatment of all patients admitted, and that they cannot augment those salaries by charging fees for treatment given in a public institution. There were two specific cases before the inspector. In one of these cases the father of the patient admitted that he was accepted as a surety for £350; that he had a farm of thirty-nine acres, and hired out a threshing machine. In the second case it was admitted the patient recently sold a farm for £860. Dr. T. E. O'Connor, medical officer of the Scariff hospital, denied that treatment had been refused in either case because of non-payment of his fees; the patients had left the hospital without consulting him. Mr. Gaffney (solicitor) said Dr. O'Connor had the support of the whole profession in the county in his stand. The doctors, he added, objected to people well able to pay entering hospital in the guise of poor people, and so exploiting the doctors. The inspector gave it as his personal opinion that a doctor could accept a fee from a patient liable for the repayment of full maintenance charges.

#### SCHOOL INSPECTION IN COUNTY DERRY.

Dr. Mary A. Long, medical officer in connexion with the County Derry Regional Education Committee's health and well-being scheme, has issued her report on the first year's work, in which she states that, notwithstanding the distrust with which this new service was regarded, many of the school managers, and most of the teachers, were most helpful and interested, and assisted in every way in winning the sympathy of the parents and children. Owing to the number of schools (223) and the large number of children present at the inspections the primary visit and routine inspection were almost all that could be accomplished. Dr. Long refers to the large number of parents who attended the inspection, and who, by verbal and written inquiries, showed how interested they were in the health of the children. One striking feature of the report is the high percentage of children found to be suffering from (1) throat and nose ailments, (2) defective teeth, (3) eye affections, (4) anaemia. Of 13,088 children medically examined, 51 per cent. were physically deficient. The condition of the children's teeth is stated to be appalling; the number who washed their teeth or have any attention paid to them is small. In one or two of the schools where the necessity of personal hygiene is taught the results are very creditable. Few children were found to be badly nurtured; many, however, were poorly nourished, and, although not suffering from any definite ailment, their power of resistance to disease was diminished. It was discovered that this was due not to want of food, but to improper feeding. Many of the families have tea four or five times a day, and in very few houses is porridge used. In such cases an amended dietary was recommended. In the Magherafelt area there were 151 verminous cases, 647 cases of defective teeth, 552 cases of tonsils or adenoids, 315 cases of eye disease, 287 cases of anaemia, 59 cases of skin disease, and 162 cases of ear trouble; other cases included tuberculosis, nervous diseases, deformity, heart disease, gastritis, nephritis, bronchitis, 4 mentally defective, and 21 unclassified cases. In the Coleraine area there were 95 verminous cases, 468 of defective teeth, 360 cases of tonsils and adenoids, 142 of anaemia, 301 of eye trouble, 53 of skin disease, 72 of aural disease, 54 of bronchitis, and a number of other unclassified diseases. In the Derry-Limavady area there were 228 verminous cases, 752 cases of defective teeth, 620 cases of tonsils and adenoids, 240 cases of anaemia, 263 cases of eye trouble, 88 cases of skin disease, 91 cases of aural disease, 54 cases of bronchitis, 100 cases of phthisis, 49 cases of non-pulmonary tuberculosis, 2 mentally defective cases, and a number of other unclassified diseases. Attention is also drawn to defects of sanitation, of seating, of heating, and to overcrowding in many schools.

## Correspondence.

### THE PERIOD OF INFECTIVITY OF WHOOPING-COUGH.

SIR,—With reference to Dr. Devereux's inquiry (September 18th, p. 542) the following details may be of interest.

At the Stato Serum Institute in Copenhagen the examination for Bordet's bacillus has been made as a routine since 1916, and the method has been used regularly both by hospitals and by practitioners.

The cases of whooping-cough which during the years 1916-20 have been diagnosed either clinically or by the finding of Bordet's bacillus, and for which sufficient information has been available, behaved as follows as to the finding of Bordet's bacillus on a single examination:

|                               | A.  | B.           |
|-------------------------------|-----|--------------|
| Catarrhal phase ...           | 134 | 75 per cent. |
| Spasmodic phase, 1st week ... | 277 | 57           |
| " " 2nd " ...                 | 201 | 61           |
| " " 3rd " ...                 | 121 | 45           |
| " " 4th " ...                 | 74  | 41           |
| " " 5-6th " ...               | 107 | 9            |

A=Number of samples from whooping-cough patients.

B=Percentage of positive findings

The frequency of positive findings thus diminishes considerably after the end of the fourth week of the spasmodic phase. The experience of the last six years has given similar results. Later than six weeks only a small number of examinations has been made. In very few cases Bordet's bacillus has been found seven to nine weeks after the beginning of the spasmodic phase.

In Denmark children are kept away from the school only until four weeks have passed since the beginning of the spasmodic phase, as there seems to be but little danger of contagion after that point of time.—I am, etc.,

MARTIN KIRSTENSEN,  
Chief of Department at the Stato Serum  
Institute, Copenhagen.

September 25th.

SIR,—I am glad the question of the duration of infectivity of whooping-cough has met with a response (BRITISH MEDICAL JOURNAL, September 18th, p. 542, and October 2nd, p. 615). It is surely high time that the mere presence of a "whoop" should be eliminated as a factor in the question of duration of infectivity, since more cases than are usually acknowledged never whoop at all, while some may whoop for a very prolonged period for various reasons. I have a patient at present convalescent some months from whooping-cough who never whoops unless she is in a temper. Surely no one would suggest that on account of this the child should be excluded from school?

Several years ago Dr. Ritchie, the school medical officer in Manchester, in consultation with Dr. Niven, late medical officer of health, decided that children might be readmitted to school after four weeks' exclusion, even though the whoop had not disappeared. I think a regulation agreed upon by the two experts just mentioned could be taken as authoritative, especially since, when in close contact with the schools working under this regulation, no instance of ill effect was ever brought to my notice, in spite of the early antagonism of the teachers to the dreadful innovation, which antagonism soon disappeared.

It must not be considered that four weeks after the commencement of the whoop is the duration of infectivity of pertussis. It is probably much less. In many instances it does not extend beyond seven days from the commencement of the characteristic whoop, the main period of infectivity preceding this. Four weeks, whilst excessive as regards duration of infectivity, gave the child a satisfactory period of convalescence after what might have been a very debilitating illness.

To combat the lengthy duration of whooping which occurs in some cases, even when the original attack has been comparatively mild, we have commenced to use x-ray treatment. Dr. Bromley, the radiologist at the Booth Hall Infirmary, reports as follows:

"A dose equal to two Hampson units is given over the chest at intervals of a week for a fortnight or three weeks. The

interval is then extended to a fortnight for two more treatments, or more. The distance is 9 inches, antikatode to skin, the filter two or sometimes three millimetres of aluminium, the current three to five milliamperes, and the hardness of the tube equals five inches equivalent air-gap. The advantages claimed for this splitting of the dose is that the time factor for each treatment is shortened, an important point with very young children, and the more x-ray treatment is actually given in the whole time."

The results of this treatment, though variable, have been decidedly satisfactory, inasmuch as the number of whoops and the duration of whooping have diminished.

This matter of duration of infectivity and period of exclusion from school would afford a very valuable discussion, which might be suggested to either the Public Health or to the Diseases of Children Sections of the Annual Meeting at Edinburgh next year.—I am, etc.,

Booth Hall Infirmary, Blackley,  
Manchester, Oct. 4th.

JOHN D'EWART,  
Medical Superintendent.

#### MINER'S NYSTAGMUS.

SIR,—In the very interesting correspondence on miner's nystagmus which has been published in the JOURNAL I note that the influence of posture is not given the primary place it would appear to merit in a consideration of the pathogenesis of the condition.

The mechanism of the phenomenon of nystagmus was formerly believed to be oculomotor, due to the removal of a higher influence, such as the cerebellum, from the control of the oculomotor nuclei. We now know that the vestibular nucleus is connected to each and all of the oculomotor nuclei by fibres of the medial longitudinal fasciculus, and that nystagmus is produced by some interference in the integrity or sensitiveness of these structures.

When a miner works in a strained or unnatural position and has to look sideways at the point where he is hewing coal, an intermittent or prolonged strain is then thrown upon all of these nuclei, and sooner or later, as in intermittent or prolonged strain elsewhere, a functional disturbance is set up which yields to rest or change of occupation.

Having been engaged for some time in an investigation of vestibular function, especially in epidemic encephalitis, I feel that the importance of the vestibular control over eye movement is not sufficiently acknowledged. I should like to emphasize this by quoting a case seen through the kindness of Professor A. J. Hall of Sheffield. The patient had an external ophthalmoplegia following an attack of epidemic encephalitis, which I was able to relieve temporarily by the simple expedient of syringing the ears with cold water. Not only was the patient able to move his eyes in a limited degree in every direction, but the diplopia of which he complained disappeared. This one case is, I think, sufficient to show what is, after all, the basis of the Bárány tests—namely, that abnormal vestibular stimulation is transmitted to the oculomotor system and expressed in abnormal ocular movements.

It is not my wish to minimize the effect of poor light, etc., on the condition, but rather to suggest to investigators who see more of these cases than I do, that they might review the possibilities of the causes of miner's nystagmus being primarily postural. The letter of Dr. Ingram-Johnson published in the JOURNAL of October 2nd (p. 615) has stimulated me to take part in this correspondence and to support Mr. Snell's theory which he refers to.—I am, etc.,

Manchester, Oct. 2nd.

RICHARD I. POSTON, M.D.

#### A WARM ENVIRONMENT FOR RHEUMATIC PATIENTS.

SIR,—The heavy incidence of many forms of rheumatic disease in cold and variable climates, and the relief of pain and stiffness obtained by heat, are generally acknowledged facts. But it is not, I think, sufficiently realized that persons unfavourably affected by cold can be, and ought to be, as much as possible protected against chill. If this is true in general, it is, I am persuaded, especially true of rheumatic patients during the period occupied by physical treatment at spas, hydrotherapeutic institutions, or clinics.

Many times have I had the unfortunate experience that thermal baths have failed of their effect in England, on account of exposure to cold during the course of treatment. A frail and elderly lady, recently referred by me to one of our mineral water hospitals, delighted in the thermal baths, after which every day she felt immediate relief of stiffness and pain, but in her weak and crippled state she was unable to bear the coldness of the dressing rooms, corridors, and wards, and the treatment had to be abandoned. People who have lost their resistance to cold cannot safely be exposed to changes of temperature after leaving a thermal bath, and hence the immemorial use of the hot blanket on stepping out of the water and of the rest in bed or on the couch of a warm dressing room. Similar precautions are peculiarly necessary in our climate. The plea for warmth derives additional force from the fact that thermal treatment is available all the year round in England, and that experience shows that it is often beneficial for rheumatic persons in the colder months of the year. I am inclined to think that many cases fail to obtain optimum results at our spas from lack of a warm environment under treatment, and that, on the other hand, the good results of institutional treatment, such as that obtained at the best "hydropathics," are due to the fact that not only the treatment department but the whole building is maintained at all seasons at a constant temperature. A visit to these places is like a visit to a warm country.

At a recent congress of hydrology in Czechoslovakia interesting details were given of thermal treatment for rheumatism at certain vapour and mud baths which have been frequented since Roman times. It is unnecessary to go to Italy for evidence of the value of heat. The Celtic baths and hermetically sealed huts of Britain and the hot baths and warm houses of the Roman occupation are equally good evidence. In the Italian spas special provision is now being made for the poorer classes and for industrial workers, but Dr. Astori of Abano is careful to emphasize the lesson which I am sure we should do well to remember, that the avoidance of chill is in many cases the secret of success:

"It is of much importance in the colder months of the year, that the bath buildings, salons, and sleeping accommodation of the patient should be maintained at a constant temperature."

—I am, etc.,

London, W.1, Sept. 27th.

R. FORTESCUE FOX.

#### APPENDICITIS AND VEGETARIANISM.

SIR,—A letter under this heading appeared in your issue of September 18th (p. 545) mentioning a case of acute gangrenous appendicitis in a boy of 10, whose parents and himself were life-long vegetarians.

I think your correspondent might certainly take this case as an exception, remembering, however, that, as far as our knowledge goes, there is no cult or craft which would dare to preach immunity from appendicitis to those who follow their tenets. Any person surely, by indiscretion in diet, is liable to produce a typhilitis which may go on to appendicitis.

Since December, 1918, I have been a lacto-vegetarian—that is, I allow myself dairy produce while abstaining from all flesh food. I have been brought into touch with most of our British and many Continental vegetarians, but have not heard of a case of appendicitis amongst them—although I have been on the alert for such. One case of gangrenous appendicitis occurred in a vigorous young married man four years ago. He was intimately associated with vegetarians and was largely a vegetarian himself, but he commonly partook of moderate quantities of fish and butcher's meat.

I should like to conclude by calling attention to what was to me a highly interesting letter in the same number of the BRITISH MEDICAL JOURNAL (p. 542), where the writer referred to the work of the Medical Research Council on "Growth and diet for boys and girls of school age." He points out that although there were great results from the added milk to the dietary, those results were outstripped in the case of girls on a dietary to which wholemeal bread, "sun-maid" raisins, and butter were added, "the first and

last taking the place of white bread and margarine. This diet, or the addition, comes very near to a purely vegetarian one.—I am, etc.,

Fareham, Hants, Sept. 29th.

ARTHUR E. DRUITT.

SIR,—In the letter on this subject which appeared in your issue of October 2nd (p. 616) it is stated that the Copts of Egypt are vegetarians. This is incorrect, on the testimony of Lane's *Modern Egyptians*, vol. ii, page 290, and according to the long experience in Egypt of the present writer.

I may add that there has been no surgeon-general with access to general health statistics in Egypt during the last twenty years, nor has any report on the incidence of non-contagious disease throughout the country been published by the Department of Public Health for many years.—I am, etc.,

London, W.1, Oct. 3rd.

A. F. MACCALLAN.

#### CANCER MORTALITY AND AGE RATES.

SIR,—I am obliged to Dr. Davies and Dr. Brown for their replies to my letter published in the *JOURNAL* of September 25th (p. 579). I had already read Dr. Davies's article in *Public Health* on the comparison of cancer mortality in Hampstead and Shoreditch. A provisional analysis on similar lines between other residential and industrial districts does not result in the discrepancy he finds. I understand from Dr. Davies's article that he suggests further investigation before arriving at a definite conclusion. The authors of "An investigation into the statistics of cancer in different trades and professions" (Medical Research Council Special Report No. 99) find that their figures "give no support worth mentioning to the idea that better living predisposes to a higher cancer death rate." A recent report on "Cancer of the Breast" (Ministry of Health No. 32) concludes that social status as judged by occupation has no bearing on the incidence of cancer of the breast. But if, as Dr. Davies assumes, cancer becomes more prevalent amongst the well-to-do as age advances, it would rather suggest that the onset of the disease was delayed owing to the better feeding producing a greater resistance.

The great disadvantage in drawing conclusions as to the incidence of cancer according to social position, trade, occupation, etc., is the considerable error that must necessarily be associated with such a method. The duration of the factors terminating in cancer are unknown and may extend over a long period. Hence the need for an exceptionally comprehensive investigation into the precancerous life.

In the Medical Research Council's report quoted above the figures were compiled from cards relating to male deaths from malignant disease which included the trade, etc., of the deceased. Presumably this referred to the trade at the time of death. Now many men have taken part in several trades during their lifetime, and even in the same trade the nature of the occupation may vary considerably. Again, the period during which a man is engaged in his trade is only a part of his total occupation, and factors connected with his pursuits and pastimes cannot be dissociated from his working occupation. Under the heading "Civil Service," for example, a clerk, although following a sedentary occupation, may lead a very active life outside his work, and his total activity may be cumulatively greater than a man in an active occupation, or vice versa. Many other errors may appear in such an investigation and can only be eliminated by dealing with a vast number of cases. The authors recognize this in their summary.

A similar analysis of districts differing in economic environment will show the same liability to error. A person who dies from cancer whilst living in a residential district and is presumed to be in a prosperous economic condition may have been living in very different circumstances for the greater part of his life. In such districts a further source of error is the fact that in districts associated with well-to-do residents there is a preponderance of persons in attendant services, such as domestic servants, chauffeurs, gardeners, etc., and it would be necessary to

analyse each case and apportion it to the relative social status in order to ascertain the proportion actually occurring amongst the well-to-do. Furthermore, in order to confirm the view as to overfeeding as a causal factor in the disease, it would be necessary to ascertain if the increased incidence was in fact amongst those who were overfed. Many well-to-do people are very abstemious as regards diet. The etiology of cancer is still a very complex subject. Even the alleged increase is open to doubt. That more cancer is seen now is probably correct, but this is not synonymous with an increase of cancer.

Statistically the disease has shown an increase since the first report of the Registrar-General in 1838. The graph of cancer shows a steady decline from the present time to that date, and if it could be carried back, at the same rate, previous to 1838 it would reach the base line about the beginning of the nineteenth century. That is to say, the first case of cancer would have occurred in this country about 120 years ago. As a fact cancer was, I suppose, a familiar disease long before that period.

How much of the statistical increase is due to improved diagnosis and certification it is impossible to say. In this connexion, however, it is interesting to note that the deaths notified under senile decay have been falling for many years. Might not many of these have gone to swell the cancer statistics?—I am, etc.,

Streatham, S.W.16, Oct. 3rd.

E. HUDSON.

#### SANATORIUM TREATMENT.

SIR,—A small correction is needed in reference to the letter of mine which you published in the *BRITISH MEDICAL JOURNAL* of September 25th.

After quoting from Dr. Stocks's and M. Noel Karn's "Memoir,"

"it was found impracticable to use the presence or absence of tubercle bacilli in the sputum as more than an adjuvant in diagnosis, since the number of cases in which bacilli were sought for and found was relatively small,"

I went on to say that the percentages were given as 19 for males and 11.9 for females.

I should have pointed out that these were the percentages for L3 cases only, in which the physical signs are most advanced. In L1 cases the percentages given are as low as 6.1 for males and 4.2 for females, as quoted in Dr. Gillespie's letter.—I am, etc.,

Cheshire, Sept. 30th.

E. WEATHERHEAD.

#### MEDICAL PRIVILEGE IN THE COURTS.

SIR,—The following extract from the trial of the Duchess of Kingston, charged with bigamy, in 1766, records, I believe, the first instance in which medical privilege was pleaded in an English court of law. The attitude of the judge on this occasion is exactly the same as that adopted by the authorities at the present time—namely, to refuse to recognize any such thing as medical privilege in connexion with the giving of evidence. A full account of the proceedings will be found in Howell's *State Trials*.

Mr. Caesar Hawkins, a medical practitioner, was called as a witness in the case, and the following questions were asked him.

Q. Mr. Hawkins, are you acquainted with the prisoner at the bar, and how long have you been so?

A. A great many years, I believe about thirty.

Q. Are you acquainted with the present Lord Bristol, and how long have you been so?

A. I have had the honour of knowing the Earl of Bristol nearly as many.

Q. Do you know of any intercourse between my Lord Bristol and the lady at the bar?

A. Of an intercourse certainly: of an acquaintance undoubtedly.

Q. Do you know from the parties of any marriage between them?

A. I do not know how far anything that has come before me in a confidential trust in my profession should be disclosed consistent with my professional honour.

The question was repeated.

Counsel. I trust your lordships will see nothing in my question that can betray confidential trust or dishonour Mr. Hawkins in giving it. My question is simply whether Mr. Hawkins knows from the parties of any marriage between them?

Lord High Steward. The question that was asked by counsel at the bar is whether the witness knew from any information of either of the two parties, that they were married. The witness objects to it whether he is to answer any questions that are inconsistent with his professional honour. Your lordships are to

determine whether the question put by counsel at the bar shall be asked.

*Lord Mansfield.* I suppose Mr. Hawkins means to demur to the question upon the ground that it comes to his knowledge some way from his being employed as a surgeon for one or both of the parties: and I take it for granted, if Mr. Hawkins understands that it is your lordship's opinion that he has no privilege on that account to excuse himself from giving the answer, that then under the authority of your lordship's judgement, he will submit to answer it: therefore to save your lordships the trouble of an adjournment, if no lord differs in opinion, but thinks that a surgeon has no privilege to avoid giving evidence in a court of justice but is bound by the law of the land to do it: (if any of your lordships thinks he has such a privilege, it will be a matter to be debated elsewhere but) if all your lordships acquiesce, Mr. Hawkins will understand that it is your judgement and opinion that a surgeon has no privilege, where it is a material question in a civil or criminal cause, to know whether parties were married or whether a child was born, to say that his introduction to the parties was in the course of his profession, and in that way he came to the knowledge of it. I take it for granted that if Mr. Hawkins understands that, it is a satisfaction to him and a clear justification to all the world. If a surgeon was voluntarily to reveal these secrets, to be sure he would be guilty of a breach of honour, and of great indiscretion: but, to give the information in a court of justice which by the law of the land he is bound to do, will never be imputed to him as any indiscretion whatever. Mr. Hawkins then answered the question.

The ruling of Lord Mansfield was undoubtedly correct law, and is exactly the view held by the judges to-day. It is, in addition to being legal, sound common sense.—I am, etc.,

Hove, Sept. 23rd.

L. A. PARRY.

#### ANGINA PECTORIS.

SIR,—The question of the quantity of the "i" in angina was recently mooted in a correspondence in the *BRITISH MEDICAL JOURNAL*. Your first correspondent (June 12th, p. 1012) quoted a line—

"*Hæstum ānginā tībī mīst/ūm sālē/pōscit ā/cētūm.*" in which the "i" was long. But he could not remember the author. It was pointed out that the author was Q. Serenus Sammonicus, who was writing circa A.D. 230, and that the line actually ran:

"*Anginā pērō sībī . . .*"

The quantity of the "i" here is short. In reading Sammonicus lately I found this version of the same line:

"*Anginām rēro mīst/ūm sālē/pōscit ā/cētūm.*"

Here the "i" is long, and is so in the three texts I have seen. Are we to assume that the word had become vulgarised when Sammonicus wrote? For the quantity of the "i" is undoubtedly short in both Plautus and Lucilius. Or was my text corrupt? I seek enlightenment, and remain a devoted adherent to *ānginā*.—I am, etc.,

London, S.E.1, Sept. 20th.

P. B. WILKINSON.

#### LATE RICKETS AND RENAL DWARFS.

SIR,—My attention has been called to the fact that in your review of the *Guy's Hospital Reports* in the *BRITISH MEDICAL JOURNAL* for October 2nd (p. 599) reference is made to a paper of mine on renal dwarfism. The reviewer says of my article: "after discussing the nature of so-called late rickets, concludes that most, if not all, of the cases so described have been renal dwarfs."

This is not quite the conclusion which I draw. I was discussing *post-mortem* findings and fatal cases, noting the fact that in some cases joints have been examined *post-mortem* but no record of the cause of death has been given. I wrote: "I think many, if not most, *fatal* cases of late rickets have been renal dwarfs."

In studying the clinical picture of late rickets and adolescent knock-knee cases, my own experience has been that rather more than half have been renal in origin, and the renal cases die from uraemia: I have notes of eight *post-mortem* examinations. The cases of late rickets of different etiology have not died, and I have no *post-mortem* experience from which to draw conclusions.

In trespassing on your valuable space with this letter I realize that it may appear to call attention to something which may never have been noticed: but, on the other hand, as your reviewer's words stand it leaves me open to the charge of having lost my sense of proportion because I happen to have followed the life-history of a number of renal dwarfs.—I am, etc.,

Derby, Oct. 4th.

HUGH BARBER.

#### Obituary.

DAVID EWART, O.B.E., M.D., F.R.C.S.Ed.,  
Honorary Surgeon and Ophthalmic Surgeon, Royal West Sussex  
Hospital.

WE much regret to record the death of Dr. David Ewart of Chichester, in his 62nd year. He was born at Ecclefechan, Dumfriesshire, but owing to the ill health of his father moved, in 1880, to New Zealand. He only began his medical studies in 1893, completing one year at the Otago Medical School. He then returned to Scotland, and graduated with honours as Bachelor of Medicine and Surgery of Edinburgh University in 1899. In 1902 he became Fellow of the Royal College of Surgeons of Edinburgh, and took the degree of M.D.Ed. with honours in 1907. During his career at the University of Edinburgh he won the Grierson bursar scholarship in pathology and bacteriology, and was assistant demonstrator in anatomy, pathology, and physiology. After graduating, Dr. Ewart went to Chichester in 1899 as house-surgeon at the Royal West Sussex Hospital, then the Chichester General Infirmary. Two years later he joined the late Dr. Skaife in practice, and was shortly afterwards appointed honorary surgeon to the hospital. He was responsible for the formation of a department for diseases of the eye, ear, nose, and throat, became honorary ophthalmic surgeon, and continued to hold the two posts concurrently. He took a prominent part in the reconstruction work at the hospital in 1913, and recently was made chairman of the board of management of the hospital. Dr. Ewart also held appointments as honorary consulting surgeon to King Edward VII Sanatorium at Midhurst, to the Graylingwell Hospital, and to the Bognor War Memorial Hospital. He was an honorary life member of the St. John Ambulance Association, acting at one time as one of its honorary surgeons. For his services at the Graylingwell Hospital during the war he received the O.B.E. To members of the British Medical Association the refined, grey-haired figure of Dr. David Ewart was well known. From 1907 he was a member of the executive committee of the Chichester and Worthing Division. He became chairman of the Division in 1921. He was a member of the Sussex Branch Council from 1915 to 1920, and a vice-president of the Branch in 1915. Owing to his early connexion with New Zealand, he represented the New Zealand Branch on the Council from 1909 to 1916, and the New Zealand and Fiji Branches since 1919. He was a member of the Dominions Committee from 1909 to 1916, and from 1919 to this year, and at one time was chairman of the committee. In 1921-22 he was a member of the Finance Committee of the Association, and he served on the Colonial Medical Service Subcommittee 1920-21. Dr. Ewart was keenly interested in the work of the Association and loyal to its interests. His temperament being of the gentler type, he did not display the violence of the partisan. He was of greater value in a judicial capacity than as a leader of men, and this was recognized in the long service he gave to the committees on which he served. He was indeed a country surgeon of the best type; of charming manners, great ability, sound experience, and worthy of the wide respect in which he was held. He took little part in public life beyond his connexion with the Royal West Sussex Hospital and with the British Medical Association, but he was a member of the West Sussex Insurance Committee. He leaves a widow and six children. The funeral service, conducted by the Bishop of Lewes, was attended on behalf of the Council of the Association by Dr. Lockhart Stephens.

The following tribute is from the pen of a close friend and colleague:

On Saturday, October 2nd, the ancient city of Chichester wore an aspect of general mourning; the cathedral was packed, marvellous was the collection of lovely flowers, and from all parts of the district men and women, rich and poor, crowded in to pay their last tribute of respect and affection to one whose name had become a household word among them. After twenty-seven strenuous years of work Dr. Ewart was carried to his rest.

Up to the time of his election as surgeon to the infirmary it had been customary to send to larger centres many cases requiring special skill, and in particular those demanding experience of eye, throat, and ear work. Ewart recognized the magnificent opportunity afforded to a keen and able man by a county hospital of sixty beds, the large majority of which were at that time at the disposal of his partner and himself, and set to work steadily to make himself and the hospital competent to deal with all. After a special course of training he started departments for throat and ear and also for eye work, and undertook, with increasing success, major surgery of every kind, so that by 1913 the time was ripe for further developments. The death of King Edward, and the generosity of the late Mr. W. James, gave opening for a county subscription. A first-class operating theatre, new out-patient departments, and other improvements were constructed, and formally opened by the King, the name "Royal West Sussex Hospital" being given to the reconstructed institution. With ever-increasing private and consulting practice Ewart's skill and experience grew apace. The ear and throat department was handed over to a colleague, but for major surgery and for eye work Dr. Ewart easily took premier place, and his skill and experience were in frequent demand by his medical confreres in many parts of the district. This year being the centenary of the opening of the hospital, a special effort will be made to carry out further improvements. No one so suitable as Dr. Ewart could be found to guide the fortunes of the institution at this critical time, and he had been elected in April chairman of the board of management. Unhappily, the unwearied labours of twenty-seven years, and especially the extra strain during the war, when by conversion of the county mental asylum a military hospital of 1,200 beds, staffed partly by local practitioners, was in regular use, proved too much for a constitution never robust. Subject to headaches ever since he had typhoid fever in New Zealand, a lifelong martyr to dyspepsia, most seriously ill with gastric ulcer (for which operation was done in 1922), he had lately been making an heroic struggle to carry on, in spite of a return of his old symptoms in aggravated form. This time, alas! the trouble was beyond the aid of surgery, and he passed away on the festival of St. Michael and All Angels.

HOWELL DAVIES, M.R.C.S.Eng., L.R.C.P.Lond.,  
Honorary Surgeon, Pretoria Hospital, Transvaal.

VERY great regret was felt throughout the medical profession in South Africa at the announcement of the death, on September 2nd, of Dr. Howell Davies. He had contracted pneumonia a fortnight before, and was nursed at first in his own home in Arcadia, Pretoria, his colleagues in the town remaining with him by turn day and night. On September 1st removal to hospital became imperative, the condition having become complicated with septicæmia and meningitis.

Dr. Davies, who was 55 years of age, was born in Wales, and received his medical training at St. Bartholomew's Hospital. He went to South Africa during the Anglo-Boer war as a civil surgeon. In the latter part of that war he was in charge of the concentration camp at Irene, near Pretoria. At the conclusion of hostilities he returned to Wales, but after a few months at home he was back in the Transvaal, and commenced private practice in Pretoria. He married Miss Mabel Chatfield of Kimberley, and they had three sons and a daughter. Two of the sons are engaged in cotton-farming in the Northern Transvaal. Dr. Davies had been honorary surgeon to the Pretoria Hospital for the past eighteen years, and chairman of the House Committee for five years. He was on the board of the Leper Asylum, and at one time on the board of the Mental Hospital. He was a member also of the board of the Victoria Cottage Maternity Hospital. For many years he was district surgeon of Pretoria. Folk in the country round about greatly regretted the day when his private practice in Pretoria town became so heavy that he had to relinquish the district surgeoncy, and could no longer visit them on their outlying farms. He was president of the Pretoria Branch of the British Medical Association, and at the

twentieth South African Medical Congress last year was elected president for the ensuing year, and was to have presided next month at the congress which is to be held at Pretoria. A hard and conscientious worker, kind-hearted and generous to a fault, his loss will be felt far outside the bounds of the medical profession.

P. J. S. NICOLL, M.D., C.M.,  
Physician, Queen Mary's Hospital for the East End.

DR. PATRICK JOHN SMITH NICOLL, who was for thirty-four years a well known medical practitioner in Stratford, London, died suddenly at Braemar, Aberdeenshire, on September 25th. He graduated M.B., C.M. at the University of Aberdeen in 1887, and in 1891 proceeded to the degree of M.D. After acting as assistant in various practices he joined in partnership the late Dr. Arthur Drake at Stratford. He held the appointments of medical officer to the Post Office, local medical officer to the London County Council, and medical officer to the West Ham education committee, and was also a certifying medical officer under the Mental Deficiency Act. He took an active interest in the work of the British Medical Association and was secretary of the Stratford Division for fourteen years. He was a Justice of the Peace for West Ham, and was a keen Rotarian, being the first vice-president of the West Ham Rotary Club. His greatest interest in life, however, was undoubtedly his work in connexion with the development of Queen Mary's Hospital. About thirty years ago he was elected a medical officer to what was then the West Ham Hospital, succeeding Dr. Sanders, who retired on being elected full-time medical officer of health for West Ham. At this time the hospital had about sixty beds. Dr. Nicoll from the first gave special attention to the administration of the hospital, which he recognized was totally inadequate for the requirements of a great and growing population, and spared no pains to further its extension. It was largely through his influence that funds were obtained for the building of an additional block containing forty beds, an operating theatre and casualty department, and residential accommodation for medical officers and nurses. When this extension was opened the staff was reconstituted and Dr. Nicoll was appointed the first physician, and became chairman of the honorary medical staff, which posts he held till his death. He was a member of the committee of management from the time of his appointment and had been vice-chairman for the last ten years.

A colleague writes: Dr. Nicoll's capacity for influencing any with whom he came in contact was much above that of most men. His friendships once made were kept to the end. The local esteem in which he was held was shown by the very large congregation who attended the memorial service held at St. John's Church on September 29th. His loss will be much mourned by a large circle of friends and patients, by whom he was respected and beloved.

DR. WILLIAM KERR PEDEN, who died suddenly while engaged in his professional work, was born at Galston sixty-eight years ago. He graduated M.B., C.M.Glas. with honours in 1879. After holding the posts of house-physician and house-surgeon to the Western Infirmary, Glasgow, he served for five years as surgeon to the Blantyre Mission in East Africa. On resigning his appointment to the Mission he spent some time in post-graduate medical study in Vienna. In 1886 he returned to Glasgow, and after a short period in partnership with the late Dr. James K. Kelly, he set up in practice on his own account. Dr. Peden, who was a member of the Glasgow Southern Division of the British Medical Association, is survived by a son and a daughter, the former being a member of the medical profession; his younger son was killed during the war.

DR. WALTER RICHARD HUGH SMITH of Shrewsbury died on September 19th. He was educated at Dublin University, where he graduated M.B. in 1902, and obtained the L.M. at the Rotunda Hospital, Dublin. He proceeded M.D. in

the following year. After serving for eleven years as second assistant medical officer to the Lancashire County Asylum, Whittingham, he was appointed senior assistant medical officer to the County Asylum, Shrewsbury, in February, 1914. On the outbreak of the war he joined the R.A.M.C. and served in India as specialist in mental disease, with the temporary rank of captain. He was a member of the Shropshire and Mid-Wales Branch of the British Medical Association and of the Royal Medico-Psychological Association.

## Universities and Colleges.

### UNIVERSITY OF OXFORD.

THE degree days in the coming academic year are as follows: *Nicholaicus Term, 1926*: Thursday, October 21st; Saturday, November 27th; Friday, December 17th. *Hilary Term, 1927*: Thursday, January 27th; Saturday, February 19th; Saturday, April 9th. *Trinity Term, 1927*: Thursday, May 5th; Saturday, June 11th; Friday, July 1st; Saturday, July 23rd; Saturday, August 6th.

### University Scholarships in the School of Medicine.

The following awards of scholarships in medicine were announced at the close of the last session:—*Theodore Williams Scholarship in Anatomy*: G. H. Bateman, University College, and J. H. B. Beal, University College (equal). *Theodore Williams Scholarship in Physiology*: P. B. C.okes, University College, and J. H. Hunt, University College. *Theodore Williams Scholarship in Pathology*: H. E. Maussel, B.A., Pembroke College; *proxime accessit*, J. A. Ferguson, B.A., Queen's College. *Radcliffe Scholarship in Pharmacology*: F. Hawking, University College.

### VICTORIA UNIVERSITY OF MANCHESTER.

THE following candidates have been approved at the examination indicated:

D.P.H. (Part D).—Mary Evans. (Part ID).—J. Rigby, H. M. Turner.

### UNIVERSITY OF GLASGOW.

THE following candidates have been approved at the examination indicated:

FINAL M.B., CH.B.—W. Allan, D. F. Anderson, G. Armour, J. C. Baird, P. M. I. Baird, R. B. Barr, H. Barton, J. Rinnie, J. Black, A. M. Brown, D. W. Buchanan, J. Burns, D. Chisholm, D. D. Clarke, Martha Cleland, W. Clement, E. A. M. Connal, A. Cumming, D. M. Cunningham, J. C. Cutlbert, J. Dunn, A. C. Ewing, Jessie A. C. Flett, Dorothy M. Forsyth, G. Gemmill, C. Gilmour, Margaret A. Glass, M. Gorfunkel, Mary G. Gorrie, Charlotte A. Gunson, J. Hamilton, J. A. Kemp, H. R. Kidd, J. E. W. Lee, D. P. Leiper, S. R. Lipchinsky, R. Logan, S. Lurie, C. E. B. Lynch, R. H. B. McCine, Mary I. McGregor, M. MacGregor, W. G. McKay, C. C. McKenzie, W. G. MacLean, T. H. McOwat, M. Manderson, J. Marzoyles, A. G. Mearns, Isabella A. Milne, L. Morrison, G. M. Muirhead, J. G. Murdoch, M. Nafatalin, J. O'Hara, T. M. Orr, H. H. Pinkerton, W. T. Rankin, D. M. Reid, G. Rowison, J. P. Seemple, G. Shearer, A. Shepherd, J. W. Shepherd, G. S. Sinclair, A. B. Smith, J. L. Smith, R. B. Smith, W. C. Smith, Eliza M. K. Stevenson, A. R. S. Stewart, M. G. Tallach, G. R. Taylor, A. Thomson, Margaret T. Tindal, H. Vost, L. A. Watson, W. Wilson, J. Wythe, H. B. Young, W. A. Burnett, R. A. Campbell, A. Esterman, D. MacCallum.

Distinction in surgery.

## The Services.

### DEATHS IN THE SERVICES.

Lieut.-Colonel Charles Barromco Jennings, R.A.M.C.(ret.), died on May 30th, aged 79. He was born on November 4th, 1846, and took the L.R.C.S.I. in 1867, and the L.K.Q.C.P. in 1868. Entering the army as assistant surgeon on March 31st, 1868, he became surgeon lieutenant-colonel after twenty years' service, was placed on half-pay on August 10th, 1892, and retired on April 26th, 1895.

Fleet Surgeon Christopher Harrey, R.N.(ret.), died at Rickmansworth on September 12th. He was educated at Westminster Hospital, and after taking the Edinburgh double qualification in 1879, entered the navy, attaining the rank of fleet surgeon on November 28th, 1890.

Lieut.-Colonel Patrick Mullane, Bengal Medical Service(ret.), died on June 13th, aged 72. He was born on March 12th, 1854, at Ballynora, co. Cork, and was educated at Queen's College, Cork, graduating as M.D. and M.Ch. in the Royal University, Ireland, in 1880. Entering the I.M.S. as surgeon on April 2nd, 1881, he became lieutenant-colonel after twenty years' service, and retired on November 1st, 1901. Except for a brief period acting in civil employ in Lower Bengal, his whole service was spent in military employ. He served in the Burma war in 1885-87, taking part in the operations of the second and sixth brigades, and received the frontier medal with two clasps. He also served on the North-West Frontier in the first Miranzai expedition of 1891; in the Chitral campaign of 1895, at the relief of Chitral (medal with clasp), and in the Tirah campaign of 1897-98, including the actions of Dargai and of the Sampaghe and Arhangha Passes (two clasps). His elder brother, Jeremiah Mullane, entered the I.M.S. in 1877, and died at Dibrugath on November 10th, 1937.

## Medical News.

THE annual service of the Guild of St. Luke will be held in Westminster Abbey on Sunday, October 17th, at 6.30 p.m., when the sermon will be preached by the Rev. Canon Sopwith. Members who propose to attend are invited to wear academic dress and to robe in the Jerusalem Chamber. They are requested to notify the secretary, c/o Miss J. S. Moore, King's College, Strand, before October 11th, from whom also a limited number of tickets for other members and friends may be obtained. On October 18th (St. Luke's Day) the annual corporate communion will be held at Grosvenor Chapel, South Andley Street, W.1, at 8.15 a.m., the celebrant being the Rev. Francis Underhill, Acting Warden of the Guild; a private room will be reserved at Lipton's Café, 484, Oxford Street, for a communal breakfast (price 1s. 6d.) if sufficient members signify to Miss Moore their desire to attend. On the evening of the same day the Provost will be at home to members of the Guild at 5 o'clock, and the annual general Chapter will be held at King's College at 5.30 p.m. Chapters will be held on November 16th, when Mr. E. B. Turner will give an address on spiritual healing, and on December 21st, when the Rev. L. C. Downing, of the Industrial Christian Fellowship, will speak on problems connected with religion and industry; both these chapters will commence at 5.30 p.m., at King's College. A special service of thanksgiving for health and of prayer for the sick and suffering will be held in St. Martin's Church, Trafalgar Square, London, on October 18th, at 7.45 p.m. The sermon will be preached by Dr. Arthur Lankester, who has been engaged in missionary work in India, and members of the medical and nursing professions are specially invited.

THE annual medical service in Liverpool will be held in the Cathedral on Sunday, October 17th, at 3 p.m. The sermon will be preached by the Bishop of Oxford (Dr. T. B. Strong), and the offertory will be on behalf of the Royal Medical Benevolent Fund. The honorary treasurer, Mr. J. Ernest Nevins, 32, Prince's Avenue, Liverpool, will be pleased to receive donations to this deserving fund from those who may not be able to be present at the service. Seats will be reserved for medical men, who are asked to wear academic costume, and their friends. Application for these seats should be made not later than October 11th to Dr. John Owen, 11, Rodney Street, Liverpool.

THE Fellowship of Medicine has arranged a series of lectures on emergencies in medicine and surgery, the first of which will be delivered by Sir Thomas Horder at 5 p.m. on October 14th, at 11, Chandos Street, Cavendish Square, W. On October 15th, at 5 p.m., Mr. M. L. Hine will give a lecture-demonstration on the red eye and the significance of circumcorneal injection, at the Royal Westminster Ophthalmic Hospital. Both the lecture and demonstration are open to members of the medical profession, without fee. A three weeks' course in laryngology, rhinology, and otology is in progress at the Central London Throat, Nose and Ear Hospital. Three courses, lasting a fortnight, begin on October 18th. These are a combined whole-day course in diseases of children in which the Paddington Green, the Victoria Hospital, and the Children's Clinic are participating; a course in gynaecology at the Chelsea Hospital for Women; and an afternoon course in urology at St. Peter's Hospital, where there will be clinical work in the out-patient department, including cysto-copies and a daily lecture on various phases of disease of the urinary tract. A course of eight lecture-demonstrations is being given at the London School of Tropical Syllabuses, the General Course Program, and its Journal, may be obtained from the Secretary of the Fellowship, 1, Wimpole Street, W.1.

AT a special meeting of the Andover Town Council on October 1st, the honorary freedom of the borough was conferred upon Councillor E. A. Farr, J.P., in recognition of his services as mayor for three successive years and the great part he has taken in bringing to a successful issue the new war memorial hospital of which he is senior medical officer. An illustrated account of the hospital was published in the JOURNAL of July 10th, 1926 (p. 74).

THE medical conference from November 3rd to 7th inclusive termed "Journées Médicales de Montpellier" will include the commemoration of the centenary of the discovery of bromine by Balard. Discussions will be held about military hygiene and the organization of medical societies; numerous excursions have been arranged. Full information may be obtained from the secretary, Dr. Desfour, 8, Rue Emile Zola, Montpellier.

DR. ALEXANDER JOE, on leaving the Edinburgh Public Health Department to take up the duties of medical superintendent of the North-Western Fever Hospital, Hampstead, has been presented by his colleagues with a silver cigarette box.

THE annual dinner of the Royal Society of Medicine has been fixed for Thursday, November 18th, at 8 p.m., at the Hotel Victoria, Northumberland Avenue. The Prime Minister has consented to be the society's guest of honour if his Governmental duties permit.

THE People's League of Health has arranged the following series of lectures to be delivered at the house of the Medical Society of London, 11, Chandos Street, Cavendish Square, at 6 p.m.: Eight lectures on the mind and what we ought to know about it, commencing on November 1st; seven lectures on "Diet: what we should eat and why," commencing on November 3rd. Application for tickets should be made to Miss Olga Nethersole, R.R.C., 12, Stratford Place, W.1.

DURING the third international congress for first aid, held at Amsterdam on September 8th, an international society for first aid was founded by the establishment of a permanent commission with its seat at Amsterdam.

At a sessional meeting of the Royal Sanitary Institute, on Friday, October 22nd, in the Town Hall, Dover, Dr. Joseph Cates, County M.O.H. Surrey, will open a discussion on "Experiences in diphtheria immunization," and Dr. A. B. McMaster, M.O.H. Dover, will open a discussion on "Port sanitary administration." The chair will be taken at 7.30 p.m. by Professor H. R. Kenwood.

THE first meeting of the seventy-first session of the West Kent Medico-Chirurgical Society will take place at the Miller General Hospital to-day (Friday), at 8.45 p.m. After the business of the annual general meeting has been disposed of clinical cases will be shown and discussed. At the meeting on November 12th Mr. Harold Chapple will read a paper on abdominal pain in women, and on December 10th Dr. Robert Hutchison will deliver the Purvis Oration, his subject being "Prognosis."

TWO Chadwick lectures on the development and present state of public health in Germany will be given by Professor Dr. Abel, Director of the Institute of Hygiene, University of Jena, on Tuesday, October 19th, at 5 p.m., and Wednesday, October 20th, at 8 p.m., in the Barnes Hall, Royal Society of Medicine, 1, Wimpole Street, W.1. At the first lecture Sir William J. Collins, K.C.V.O., M.D., Chairman of the Chadwick Trustees, will preside, and at the second lecture Sir Arthur Newsholme, K.C.B., M.D. Admission is free (without tickets).

THE Section of the Royal Society of Medicine for the Study of Disease in Children will hold a meeting, postponed from last session, at Birmingham on Saturday, October 30th. Clinical cases will be shown at the Children's Hospital, Ladywood Road, at 2 p.m., and biochemical and pathological demonstrations will be given at 4.30 p.m.

THE annual dinner of the Chelsea Clinical Society will take place at the Café Royal, Regent Street, under the chairmanship of Dr. Ernest Young, on Tuesday, October 26th, at 7.30 p.m. At the meeting of the society on November 16th there will be a discussion on encephalitis lethargica, and on December 21st a discussion on septicæmia.

THE annual dinner of the Brussels University Medical Graduates' Association will be held on Thursday, October 28th, at the Langham Hotel, Langham Place, W.1, at 7.30 p.m. Price of tickets 12s. 6d., exclusive of wine. Holders of the M.D.Brux. degree who have not received a circular and pamphlet are asked to communicate with the honorary secretary of the association, Dr. A. D. Woolf, 11, Chandos Street, Cavendish Square, W.1.

THE annual meeting of the Medical Sickness, Annuity, and Life Assurance Society will take place at the offices of the company, Lincoln House, 300, High Holborn, W.C., on Monday, October 11th, at 4 p.m.

A LECTURE on ultra-violet light, arranged by the Chartered Society of Massage and Medical Gymnastics, will be given in the library of the Royal Victoria Infirmary, Newcastle-on-Tyne, on Wednesday, October 13th, at 6 o'clock, by Dr. Justina Wilson. Members of the medical profession are invited to attend.

DR. HENRY VUILLET has succeeded Professor C. Roux in the chair of clinical surgery and as head of the surgical department of the Cantonal Hospital at Lausanne.

IN Germany during 1925, 12,476 cases of enteric fever were notified, as compared with 14,439 in the previous year. The diphtheria incidence also fell, there being 35,296 notifications in 1925, as compared with 38,256 in 1924. Acute poliomyelitis diminished from 507 cases in the previous year to 387 cases in 1925; rabies from 48 to 20, and trichinosis from 13 to 9. Encephalitis lethargica was more prevalent, there being 217 cases reported in 1925, as compared with 156 in the previous year. A sharp increase in trachoma occurred, the figures being 2,777 in 1925, as compared with 1,800 in 1924 and 1,200 in 1923. This increase is attributed to a large influx of Polish workmen last year.

CONSEQUENT on the resignation of Sir Charles Ballance from the post of chief surgeon to the Metropolitan Police, Dr. Maurice A. Cassidy has been appointed physician and chief medical officer. Mr. C. Max Page has been appointed consulting surgeon and Dr. H. B. Russell deputy physician to the Metropolitan Police.

THE late Dr. Louis Ernest Desnos, whose death was announced in the JOURNAL (January 9th, p. 74), has left a legacy to the Académie de Médecine, of which he was a member, to found a triennial prize of 3,600 francs to enable a doctor or resident in a Paris hospital to undertake a scientific mission abroad.

A MEMORIAL was recently unveiled at Lebanon, Connecticut, to Dr. William Beaumont, the pioneer American physiologist, who studied gastric digestion through an accidental fistula on Alexis St. Martin.

IN an annotation published on September 18th (p. 536) we referred to the work of the National Institute for the Deaf. We have now received the report of the conference of agencies engaged in the welfare of the deaf, held in London on June 10th last, and called together by the institute. Copies, price 1s. post free, may be obtained from the Secretary, at the office, 67, Frith Street, Soho Square, W.1.

STATISTICS of births and deaths in the United States are incomplete owing to a defect which the efforts of the United States Census Bureau and of the American Medical Association have not yet been able to remedy. From a manifesto issued by the former and published by the JOURNAL of the latter it appears that of the forty-eight States all, with three exceptions, have adequate registration laws, but that in fifteen of them they are not properly enforced. It is hoped that by 1930 it will be possible to abolish the term "registration area" and to substitute for it "national registration."

MR. SAMUEL WILLIAM FARMER, J.P., of Little Bedwyn, Wilts, has left estate of the gross value of £404,330, with net personally £381,341. Subject to certain legacies and some specific bequests, the residue of the property is bequeathed for the benefit of persons of either sex, particularly and especially, but not necessarily or exclusively, for the upper middle professional classes, who, through ill health or by reason of advancing years, are incapable of earning their own livelihood, or for such educational purposes or for the benefit of such hospitals, nursing or convalescent homes, or other similar charitable objects as his trustees may think fit.

THE office of the National Association for the Prevention of Tuberculosis has been removed from 20, Hanover Square, W.1, to 19, Tavistock Square, W.C.1 (Telephone: Museum 2577).

THE through express Calais-Vintimille (in connexion with the 11 o'clock service from Victoria) will be reintroduced on October 11th. Accommodation can be reserved at the P.L.M. Railway Offices, 173, Piccadilly, or through any tourist agency.

ON the completion of twenty-one years' service Dr. B. H. Slater, medical superintendent of St. Luke's Hospital, Bradford, has been presented with a silver tea service by the hospital staff.

THE late Lieut.-General Sir William Leishman, K.C.B., F.R.S., Director-General of the Army Medical Services, has left estate of the gross value of £7,893.

DR. HERMANN BREHMER, a well known writer on tuberculosis, celebrated his hundredth birthday on August 14th.

THE German Society for the History of Medicine and Natural Sciences, whose organ, *Mitteilungen zur Geschichte der Medizin und der Naturwissenschaften*, is well known to medical historians, celebrated the twenty-fifth anniversary of its foundation last month.

ELEVEN cases of trichinosis with one death occurred at Vienna and Innsbruck in the first six months of this year, as compared with seven cases and three deaths during the whole of 1925.

IN the Dutch Indies 894 fatal cases of plague occurred between March 21st and May 15th.

WE have received a copy of *Die Arzfrage in der Sozialversicherung*, which is a series of papers written, under the editorship of Dr. Hubert Korkisch of Prague, by seventeen prominent representatives of insurance societies and medical and scientific bodies in England, France, Germany, Austria, Switzerland, and Czecho-Slovakia, dealing with the question of national insurance in these countries.

THE Department of Justice at Washington has decided that the Wassermann test shall be performed on all the inmates in the Federal prisons.

A GREAT epidemic of trachoma has broken out in the region of Kharkov. Out of every 1,000 ophthalmological cases 200 are suffering from the disease.

## Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **The Editor, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1.**

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the BRITISH MEDICAL JOURNAL must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the JOURNAL, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBERS of the British Medical Association and the BRITISH MEDICAL JOURNAL are MUSEUM 9861, 9862, 9863, and 9864 (internal exchange, four lines).

The TELEGRAPHIC ADDRESSES are:

EDITOR of the BRITISH MEDICAL JOURNAL, Aitiology Westcent, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate Westcent, London.

MEDICAL SECRETARY, Mediscera Westcent, London.

The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 4737 Dublin), and of the Scottish Office, 6, Drumsheugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 4361 Central).

### QUERIES AND ANSWERS.

#### HYDROA.

"W. L." asks for advice in the treatment of a boy, aged 3½ years, who suffers from hydroa. The condition is of six weeks' duration, and recurring on the back, legs, and about the elbows. Arsenic, bismuth carbonate, calcium lactate, magnesias, have been tried internally without success, and an egg-free diet has had no effect.

#### PRURITUS.

DR. T. C. HUNTER (Newcastle-on-Tyne) writes in reply to "W. A." (September 25th, p. 532), who asked for suggestions in the treatment of pruritus, with thickening of the skin of the palms of the hands: I found an eruption of this character, which was probably psoriasis, disappear like magic by rubbing in equal parts of ung. picis, ung. hydrarg. ammon. chlor., ung. salicylic. This treatment was suggested by Dr. Wells Patterson. The eruption, which was extensive and on the instep of the foot, did not recur.

#### NERVOUS VOMITING.

"H. W. B." asks for suggestions for the treatment of a young woman, aged 23, of good physique and with no apparent disease of the alimentary tract, who suffers from vomiting after excitement. After an evening dance or an important golf match she sleeps soundly as usual, but awakes about 5 a.m. with a violent attack of vomiting and sickness, which continues for five or six hours, unaccompanied by pain or headache, and ending spontaneously, with no after-effects. The vomit is watery, and the attacks occur irrespective of whether she has had supper or not. The condition has lasted for about two years, in spite of various forms of treatment, including sodium bromide at bedtime.

#### X-RAY TREATMENT OF RINGWORM.

DR. CHRIS. J. MCSWENEY (Cardiff) writes in reply to "T. E. R." (September 11th, p. 511): The use of aluminium filters is theoretically an advantage in eliminating the dangerous soft rays and so minimizing the risks of resultant radio-dermatitis. If the Sabouraud pastille is at half skin distance it will probably be between the filter and the tube, and so will receive unfiltered rays. Its colour will therefore be no guide as to the quantity of rays which has reached the scalp. If the pastille is on the skin—the method originally employed by Hampson in 1911—it of course receives filtered rays, and its colour can be matched as usual with the Lovibond tintometer, against fractions of Teinte 8. Kienböck's strips, which are laid on the scalp, furnish probably the simplest method of calculating the dose of filtered rays. Whatever method is employed the time of exposure will be increased—even by 30 to 50 per cent., according to the thickness of aluminium used. As to whether filtered rays give more uniform epilation, I do not think this has ever been claimed for them. My own experience is that unfiltered rays, proceeding from a hard tube, and working with standard conditions of time, distance, voltage, and milliamperage, are more reliable.

#### WATERY EYES.

DR. L. J. GREEN (South Tottenham) writes: With reference to "A. G. F.'s" inquiry (October 2nd, p. 619) as to the origin of his watery eyes, the condition may be due to (1) a drainage fault in the lacrimal passages, perhaps associated with the presence of a mucocele of the lacrimal sac, or (2) a spasmodic hypersecretion through abnormal stimulation via the branch of the fifth nerve which supplies the lacrimal gland. Of these, the

first seems the more likely. The most common sites of obstruction to the flow of tears are at the lacrimal puncta, and in the course of the lacrimal duct—for example, in cases of intranasal disease. The condition could be brought about by repeated "colds." It can soon be determined whether the puncta are too small, and obstruction in the lacrimal duct is demonstrated by carefully passing a lacrimal probe. If a mucocele of the lacrimal sac is present the conjunctiva will be flooded with fluid every time the sac is pressed upon and thereby emptied. "A. G. F." should have the above points investigated.

#### INCOME TAX.

##### Sale of Investment.

"R. L. T." has been requested to state the date on which he sold a holding in War Loan, and how the money has been invested. Are these requests justified?

It has to be remembered that the inspector of taxes has very little legal ground for making inquiries direct of taxpayers. He is entitled to examine the returns, however, and the making of relevant inquiries enables him to agree with the assessments before they are formally authorized by the Commissioners, and thereby to avoid trouble at a later stage to all concerned. The first inquiry is evidently directed to ensuring that the assessment is technically correct and that any appropriate adjustment is made in the previous year's assessment; "R. L. T." may be entitled to some relief if he sold the War Loan in that year. The second inquiry rests on less obvious grounds. Presumably the inspector desires to ensure that no new income has been overlooked. Doubtless a general reply on that point will serve—for example, that it has been reinvested in such a way as to produce income taxed at its source.

##### Notifications to Panel Patients.

"J. R." explains that his Panel Committee deducted £2 14s. from his first cheque to cover the cost of the postage of notices sent to patients on his predecessor's panel intimating that he had taken over the practice. Can he deduct that amount from the full fees for income tax purposes?

No. The expense was incurred in the taking over of the practice—that is, it related, not to the working of it, but to the change in proprietorship, and as such is not allowable for income tax.

### LETTERS, NOTES, ETC.

#### HOUSE OF REST, MENTONE.

DR. D. W. SAMWAYS (Topsam, Devon) writes to call attention to the fact that invalid professional men requiring a change, and whose means are limited, are received into the House of Rest at Mentone, Riviera, at a charge of 30s. a week, all found, on application to the matron, Miss Goldie, or to Dr. Stanley Rendall, or to Dr. Samways, Mentone, during the winter season.

The home, we believe, is a philanthropic undertaking (apart from the charge of 30s. weekly), and is meant to help professional men who break down temporarily. It is hence useful to medical men of small means or their professional patients in like case.

#### A DANGEROUS DRUGS REGISTER.

UNDER the Dangerous Drugs Regulations, 1926, non-dispensing doctors, who have hitherto been exempt from such a requirement, must now keep a record of all "dangerous drugs" purchased or otherwise obtained. The Register of Dangerous Drugs, published by Messrs. Woodrow and Co. (3, Cook Street, Liverpool), admirably serves this purpose in the simplest form consistent with the Regulations. Separate pages, provided with a thumb index, are set apart for the four groups of drugs and their preparations which must be registered—namely, morphine, cocaine, heroin, medicinal opium. In addition there is an excellent summary of the various regulations, 1921 to 1926, so far as they relate to duly qualified medical practitioners. The size of the Register is 10 in. by 6 in. The prices are: Bound, 6s.; post free, 6s. 6d.; or in strong Manila boards, 4s.; post free, 4s. 3d.

#### TREATMENT OF PRURITUS ANI.

DR. ERNEST WARD (Paignton) writes: Two medical men who believe themselves to have been immediately and permanently cured by a simple line of treatment have asked me to make known the method I have long used to treat this troublesome affliction. Anal pruritus arises in the great majority of cases from a perianal dermatitis, due to repeated infection during the cleansing after defaecation. To cure the dermatitis it is only necessary to avoid soiling the parts concerned. If paper is used each piece should be passed in one sweep from behind forwards, then rejected. Wool or a sponge used similarly may prove more efficient among the many sufferers from haemorrhoids, but paper will serve equally well in most patients and is vastly more convenient.

#### VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 49, 50, 51, 54, and 55 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 52 and 53.

A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 163.

## British Medical Association.

## PROCEEDINGS OF SECTIONS AT THE ANNUAL MEETING, NOTTINGHAM, 1926.

## SECTION OF MEDICINE.

F. H. JACOB, M.D., F.R.C.P., President.

DISCUSSION ON  
SOME RECENT DEVELOPMENTS IN OUR KNOWLEDGE OF THE BILIARY TRACT.

## OPENING PAPERS.

## I.—EVARTS A. GRAHAM, M.D.,

Professor of Surgery, Washington University School of Medicine; and Surgeon-in-Chief to Barnes and St. Louis Children's Hospitals, U.S.A.

MINGLED with the appreciation of the high honour which you have bestowed on me in inviting me to speak before the British Medical Association is the sense that perhaps even a greater honour has been accorded to me, a mere surgeon, in being invited to appear before the section on internal medicine.

## FUNCTIONS OF THE GALL BLADDER.

The extraordinary interest which has been displayed in the gall bladder in recent years is associated with the ever-increasing evidence that disorders involving this small organ afflict a very large proportion of adult humanity, and that they probably constitute the most frequent organic cause of dyspeptic symptoms. Yet the known normal functions of this structure seem to be relatively insignificant—namely, the regulation of pressure in the biliary system and the concentration of bile by the absorption of water. Other functions are suggested perhaps by the fact that the blood from the gall bladder drains into the portal vein and is thus carried through the liver, as if something from it is useful in the normal metabolism of the liver. But about such possible functions nothing is known at present, although Boyd<sup>1</sup> has proposed that the gall bladder absorbs cholesterol, and Sweet<sup>2</sup> has made the suggestive hypothesis that the gall bladder forms something which acts to de-esterize cholesterol esters. Sweet has also shown that in some of the animals which do not normally possess gall bladders there are innumerable saccules, resembling diverticula, projecting from the walls of the intrahepatic bile ducts. He has found a large number of these saccules in animals from which the gall bladder has been experimentally removed, and he offers the opinion that they compensate for the removal of the organ, in that each sacculo may be a miniature gall bladder. Apparently, then, the serious consequences of cholecystic disease must be concerned with phenomena apart from the disturbance of the functions of the gall bladder.

## PATHOGENESIS OF CHOLECYSTITIS.

In 1918 observations<sup>3</sup> were published which indicated that inflammatory changes in the liver were a constant accompaniment of cholecystitis. During the course of operations on the gall bladder I had removed small pieces of liver tissue for microscopic examination. These had shown uniformly a type of inflammation which was essentially a pericholangitis, chiefly apparent in the interlobular tissue, but often extending upwards to involve even the smallest bile capillaries. Even in the less severe cases of cholecystitis this hepatitis could be demonstrated. This finding has been corroborated by others, notably by Judd<sup>4</sup> and by Hoyd, Killian, and MacNeal.<sup>5</sup> In many cases of so-called cholangitis this type of hepatitis had been observed before, but the great frequency of it, amounting to an almost constant finding in cholecystitis, had apparently not been noted.

Later the microscopic examination of gall bladders removed at operation convinced me that, since often more

inflammatory change is found at the periphery than in the mucosa of the organ in what seemed to be the early and the less severe cases, too much emphasis had been placed by the

the importance of mucosal infection of cholecystitis. The clinical observations that patients with cholecystitis sometimes gave a history of having had typhoid fever had had an important influence in the development of the idea that infection of the gall bladder is due to bacteria brought to the liver by way of the portal vein, secreted in the bile, and thence carried into the gall bladder. Numerous difficulties, however, presented themselves with the acceptance of such a theory. In the first place, Cushing<sup>6</sup> and later others found that in experiments on animals it is extremely difficult to infect the gall bladder by the introduction of bacteria into its lumen unless at the same time the cystic duct or the cystic artery is tied or the mucosa injured by the introduction of foreign bodies. Moreover, both Rolleston<sup>7</sup> and Osler<sup>8</sup> showed that cholecystitis is rare during the acute course of typhoid fever, a time when supposedly the bile is teeming with typhoid bacilli. The possibility of a blood-borne infection directly to the gall bladder through the cystic artery was also suggested by many. In recent years Rosenow<sup>9</sup> has been the most enthusiastic exponent of this view.

The constancy of the finding of a hepatitis in association with cholecystitis, and the observation that in many cases the mucous membrane is less involved than the outer coats of the gall bladder, led to the thought that another pathway of infection might be important—namely, the lymphatics.<sup>10</sup> Sudler,<sup>11</sup> working in Mall's laboratory, had already in 1901 shown the very extensive anastomosis which exists between the lymphatics of the liver and of the gall bladder. The richest supply of lymphatic vessels in the gall bladder is situated immediately beneath the serosa. Therefore, cholecystitis which would occur secondarily to a hepatitis would be most likely to begin at the periphery of the gall bladder if a lymphatic extension of the infection should take place here as in other parts of the body. When this idea was put to the test of experimentation it was found possible not only to produce cholecystitis in animals by the injection of bacteria into a radicle of the portal vein, but also it was observed that the cholecystitis was most marked at the periphery of the gall bladder and that the liver showed changes similar to those already mentioned as having been found in the human. In 1921 Meyer, Neilson, and Feusier<sup>12</sup> published the results of their exhaustive experimental work on paratyphoid infections, in which they made the important observation that cholecystitis did not occur unless there were actual inflammatory lesions in the liver, in spite of the fact that in practically all of their animals the organisms could be found in the gall bladder bile regardless of whether hepatic lesions were present or not. This finding seemed to be additional corroboration of our view of the spreading of a pre-existing inflammation of the liver to the wall of the gall bladder through the lymphatic vessels. It would follow from this, then, that any condition which might induce an infection in the liver might also predispose to cholecystitis. Inflammatory lesions of the portal system would have an excellent opportunity to bombard the liver and to set up a hepatitis. It is not surprising, therefore, that clinicians have long known that cholecystitis is frequently found as a sequel of, or in association with, the most common inflammatory lesions of the portal system—such as appendicitis, peptic ulcer, and typhoid fever.

Other experiments have shown also that hepatitis will follow experimentally produced cholecystitis. The possibility of the establishment of a vicious circle between the liver and the gall bladder is therefore suggested, whereby each may reinfect the other. It is not to be inferred from these conclusions that the opinion is held that all cases of cholecystitis are due solely to a lymphatic spread from a hepatitis. Some are doubtless due to haematogenous infections of the gall bladder, and some are probably due to involvement of the mucosa first and are therefore contact infections.

In our article of 1922 on the lymphatic origin of cholecystitis we made the statement that our experiments indicated that interstitial pancreatitis is also the result of

a lymphatic spread of infection from the liver to the pancreas. This view had already been expressed by Maugeret<sup>13</sup> and by Deaver and Sweet.<sup>14</sup> It has been seriously questioned, however, by Archibald.<sup>15</sup> Recent unpublished work done in our laboratory by Kodama<sup>16</sup> supports strongly Archibald's contention that the lymphatics from the region of the gall bladder pass along anterior to the pancreas but do not actually enter it. It is probable, therefore, that the cases of interstitial pancreatitis which we obtained following experimental hepatitis and cholecystitis were not due to a lymphatic spread but might have been due to a haematogenous infection. Kodama has shown, however, that if the gall bladder becomes adherent to the surface of the pancreas, then injected fluid will pass through tissue spaces directly from the gall bladder to the parenchyma of the pancreas.

Other important results of Kodama's study of the extrahepatic biliary lymphatics are as follows:

When the superficial lymphatics of the first portion of the duodenum are injected with a solution of trypan blue and gelatin the coloured solution is found to enter the wall of the gall bladder through the lymphatic vessels which course along the common duct. If, however, the lymphatics of other portions of the duodenum—the second and third portions—are injected, the dye does not enter the wall of the gall bladder but enters the mesenteric lymph gland which is situated at the beginning of the portal vein after passing through the lymphatic vessels under the peritoneum between the duodenum and the portal vein. Conversely also, when the lymphatics of the gall bladder are injected some of the dye passes into the lymphatics of the first portion of the duodenum.

The possible bearing of these findings upon the association of cholecystitis and duodenal ulcer is obvious; and they suggest another method of pathogenesis of cholecystitis in addition to the one proposed above, which in turn has resulted from infection brought to the liver by the portal vein from a lesion in the portal system. This work of Kodama's would indicate that a duodenal ulcer might induce cholecystitis directly by means of lymphatic extension without the intervention of a hepatitis. The constancy of the finding of a hepatitis in association with cholecystitis might, then, be due in some cases to an infection of the liver secondarily to the gall bladder. Kodama has also found that the lymph which comes from the liver, gall bladder, pancreas, and first portion of the ascending colon all drains eventually into the lymph gland which is located at the beginning of the portal vein. On the other hand, the lymph from the rest of the intestine is discharged into the various other mesenteric lymph glands.

#### DIAGNOSIS OF CHOLECYSTITIS.

The diagnosis of typical cases of cholecystitis, either with or without calculi, is usually easy by means of the clinical history and ordinary physical examination. But the conditions which give rise to the typical signs and symptoms are usually late effects of disease. Obviously it would be desirable to have some means of recognizing the presence of disease before the late effects have occurred, and equally desirable would it be to have a means of recognizing the atypical and obscure cases. I shall not discuss here the use of the well known tests of hepatic function and similar methods, preferring to leave this question to those in this symposium who are better qualified than I to discuss them intelligently.

The remarkable advance in gastro-intestinal diagnosis made possible by the giving of a meal opaque to the Roentgen ray—a method first utilized by Cannon of Boston in physiological experiments—gave rise to the thought that similarly far-reaching results might be obtained if some method could be devised whereby the gall bladder could be visualized. The previous work of Abel and Rowntree,<sup>17</sup> which showed that the chlorinated phenolphthaleins are excreted largely through the liver into the bile, offered the suggestion that if atoms of bromine or iodine should be substituted for chlorine a substance might then be at hand which would not only be excreted into the bile but would also render the gall bladder opaque to the Roentgen ray.

With such ideas in mind, in the summer of 1923 W. H. Cole and I,<sup>18</sup> later in association with Copher and Moore,<sup>19</sup> undertook to investigate this problem. Because of the high atomic weight of iodine the first substance which we used

was tetraiodophenolphthalein, and we succeeded in demonstrating the fact that with this substance cholecystography is possible, at least in dogs. But because of some severe toxic reactions resulting from the use of our first preparations, which we felt might be inherent in the substance itself, we resorted to the use of tetrabromphenolphthalein, which happened to be accompanied by much less toxic disturbance than our first preparation of tetraiodophenolphthalein. Accordingly, therefore, we were exceedingly cautious about using the iodine compound in the human, and in our first publications we recommended the use of the bromine product. More careful preparation, however, showed that it was possible to manufacture tetraiodophenolphthalein free from toxic impurities; and we accordingly later recommended that instead of the bromine product. The toxic reactions are due chiefly to the phenolphthalein part of the molecule. Since the tetraiodo compound can be given in smaller doses with equally good results because of the higher atomic weight of iodine, obviously fewer toxic reactions would be expected than with the tetrabrom product. Such was found to be the case. Whitaker and Milliken<sup>20</sup> of Boston, in January, 1925, reported their good results obtained with tetraiodophenolphthalein, and recommended the substitution of that for the bromine product. Their article appeared practically simultaneously with one of ours, in which we reported the resumption of work with tetraiodophenolphthalein, but in which we exercised caution in recommending its use because of marked differences in toxicity which we had noted in samples from different manufacturers, and also because we were not certain of the stability of the substance on standing. These young men are entitled to credit for having gone ahead independently and on their own initiative in an attempt to improve the method of cholecystography, and they have helped much to popularize the procedure.

In the United States the iodine compound has almost entirely supplanted the bromine product. The use of the tetraiodophenolphthalein does not change in any way the standards of interpretation as worked out for the tetrabromphenolphthalein. Presumably the criteria of interpretation would be the same for any substance which would make the gall bladder opaque to the Roentgen ray. We have experimented with forty different substances, some of which have never been made before. These various substances have been mentioned in our publications. Of the forty different substances which we have used, eleven have been found to have the power of making the gall bladder visible. But of these eleven there seem to be only three which are suitable for clinical use; these are tetraiodophenolphthalein, tetraiodophenolphthalein, and the isomeric compound of the latter, phenoltetraiodophthalein. Recently we have found another substance, tetraiodo-isophenolphthalein, which may prove to have advantages over any of the others. But we have not yet had sufficient experience with it to be sure of its possibilities.

All three of these substances are secreted almost entirely by the bile—approximately 98 per cent. as shown experimentally in the dog. Recently we have found that phenoltetraiodophthalein not only produces good shadows of the gall bladder, but also colours the serum sufficiently after alkalization of it to make it possible to employ it as a test of hepatic function in a manner similar to the Rosenthal test with phenoltetrachlorophthalein. Therefore, by those who place confidence in the diagnostic value of tests of hepatic function, this substance may be used simultaneously for cholecystography and for tests of hepatic function. It also colours the urine after alkalization, but since only about 2 per cent. of it is secreted in the urine it will probably not be of much value as a test of renal function. The structural formulae of these two isomeric iodine compounds are as follows:

Structural formula of tetraiodophenolphthalein.

Structural formula of phenoltetraiodophthalein.

A proper conception of the interpretation and value of cholecystography in diagnosis must be based on an understanding of some of the theoretical points involved in its use. The substance used must be excreted by the liver into the bile. It must pass with the bile into the gall bladder, where it must be concentrated by the absorption of water in order to give the densest shadows. It is obvious, therefore, that the densest shadows will be found in normal subjects. It is equally apparent that there may be no shadow at all, or only a faint one, if the liver is unable to excrete the substance normally, if the cystic duct is occluded, or if the gall bladder is unable to concentrate its contents because of a diseased wall. Moreover, as bile is poured out from the gall bladder into the common duct, it is obvious that the shadow will diminish in size and gradually disappear entirely. Since the presence of food in the duodenum is accompanied by an outpouring of bile, the necessity of fasting during the period of concentration of the substance in the gall bladder becomes evident. It is seen, therefore, that cholecystography is really a means of studying the function of the gall bladder rather than an indication of the exact pathological lesions present. This method of examination provides a means of determining the state of the only two functions of the gall bladder known—namely, the regulation of pressure within the biliary tract, and the concentration of the contained bile. The former function is shown cholecystographically by changes in the size of the gall bladder, indicating distensibility and contractility; and the latter is shown by an increasing density of the shadow. Since the days of *Galen functio laesa* has been recognized as one of the cardinal signs of inflammation. Presumably, therefore, any method which detects alterations of function would denote early and even mild cases of inflammation. Cholecystography seems to possess this property.

The enthusiasm with which this procedure has been almost universally received has been astonishing. However, the method of administration of these substances which we proposed in our first publications has been considerably modified by later workers. The chief reason for this modification has been a desire to get away from the intravenous administration both because of the more complicated technique necessary and the fear of toxic reactions. Meneses and Robinson<sup>21</sup> were the first to recommend the oral administration. The method of oral administration requires the use of a protective coating of some kind to permit the substance to pass into the intestine unchanged, because the hydrochloric acid of the stomach will convert the soluble sodium salt into the insoluble free acid. If this change occurs, absorption will therefore not take place. Various capsules and other sorts of protective coverings have been advocated. I cannot here enter into a complete discussion of this phase of the subject. Excellent discussions of the various methods of oral administration will be found in the articles by Levyn and Aaron,<sup>22</sup> who have carried on extensive experiments with different kinds of protective coatings, by Whitaker, Milliken, and Vogt,<sup>23</sup> by Stewart, Einhorn, and Ryan,<sup>24</sup> and by Larimore.<sup>25</sup> In general, in the intravenous method, a slightly larger dose is used than by the oral method; the capsules are given after the evening meal, and the patient presents himself before breakfast for his first film. A meal is then taken, preferably one rich in fats in order to empty the gall bladder quickly, and other films are made about four hours later, and at about the twenty-fourth, thirty-sixth, and forty-eighth hours afterwards if the shadow still persists.

There are two serious objections to the oral method: one is the uncertainty of the amount of the substance absorbed, and the other that many toxic disturbances, such as diarrhoea and vomiting, occur. For these reasons, at the

Barnes Hospital we have adhered rather closely to the intravenous method, almost as outlined in our early papers and as carried out in Great Britain by Cohen and Roberts<sup>26</sup> with tetrabromophenolphthalein. Improvement in manufacture of the tetraiodophenolphthalein has resulted in our hands in an almost complete absence of toxic reactions after the intravenous administration. Also greater dilution minimizes the reactions, although it is not necessary to use more than 30 c.cm. of fluid if the injection is made slowly and if the vein is washed out with physiological saline or with Ringer's solution immediately after the injection is made. The latter precaution is desirable to avoid thrombophlebitis at the site of injection. The use of the new isomeric compound, the sodium salt of phenoltetraiodophthalein, however, will almost completely obviate toxic reactions. In ninety-seven successive cases in which we have used it intravenously there have been no severe reactions. Of course, as in any intravenous injection, meticulous care should be exercised in the sterility of all materials used, in the use of freshly distilled water for the solutions, and in scrupulous cleanliness of glassware. In the last 150 cases in which we used sodium tetraiodophenolphthalein there was no case in which any alarming reaction occurred. We have personal knowledge of several thousand cases in which the intravenous method has been used, and we know of no death attributable to the substance.

Our own technique is as follows:

For the adult of average size 3 or 3½ grams of the sodium salt of tetraiodophenolphthalein, or 2½ grams of the sodium salt of phenoltetraiodophthalein, are dissolved in from 30 to 50 c.cm. of water, filtered, and sterilized in a boiling water bath for fifteen minutes. The solution is slowly injected with a syringe in the morning between 8 and 9 o'clock, preferably in two equal doses, half an hour apart. Dividing the dose tends to eliminate any risk of a toxic reaction. If given very slowly, however, over a period of ten or fifteen minutes, in one dose there is but little danger of a reaction. Case has recommended the prompt injection of 0.5 c.cm. of adrenaline if any symptoms of a severe reaction occur, such as fall in blood pressure. We have found this helpful in the few cases in which it seemed necessary. Breakfast is omitted in order that the duodenum may be empty during the period of concentration in the gall bladder. For lunch the patient may have a liquid diet, but it should contain little or no protein or fat. The evening meal may be taken as usual. We formerly employed large doses of sodium bicarbonate by mouth, because Cole<sup>27</sup> showed in some experimental work on animals that the reduction of the gastric acidity tended to reduce the amount of bile discharged into the duodenum. He was able to obtain this finding even when care was taken to exclude the passage of gastric contents into the duodenum. Lately, however, we have abandoned the use of the bicarbonate because it has seemed unnecessary. Roentgenograms are made four, eight, and twenty-four hours after the injection. Dr. Sherwood Moore, the director of our department of radiology, prefers not to use the Potter-Bucky diaphragm. A series of films is essential in order to gain information concerning the concentrating function and the changes in size of the gall bladder.

An important modification of this procedure has been made by Milliken and Whitaker,<sup>28</sup> who give a meal containing fat in order to determine the ability of the gall bladder to reduce its size promptly. This is based on important work by Boyden<sup>29</sup> to which reference will be made later. Case<sup>30</sup> gives his injections at 5 p.m. in one dose, dissolved in 75 to 100 c.cm. of Ringer's solution. The patient takes his evening meal as usual. Films are taken before breakfast. The patient then eats a meal, including egg yolk or milk and cream, and he returns at about noon for more films, which conclude the examination. Wilkie and Illingworth<sup>31</sup> prefer to make the injection between 8 and 10 p.m. after the omission of the evening meal. Pribram, Gruenberg, and Strauss<sup>32</sup> have recommended the use of a preliminary injection of pituitrin in an attempt to empty the gall bladder first.

Accuracy of interpretation of the cholecystograms, obviously, will improve as our experience increases. It is important also to realize that accuracy of interpretation depends very largely upon experience with the particular method of administration. One who is familiar with the results of the intravenous method will often be puzzled by those obtained by the oral method if his experience with the latter has been limited. Normally, after the intravenous method described above a faint shadow of the gall bladder will usually be visible in about four hours. At eight hours it will have increased in density and will often be somewhat smaller, probably because of reduction in volume by concentration. At twenty-four hours the shadow will usually be nearly or completely gone. If, however, no food at all has been taken since the injection the twenty-four-hour shadow may be the densest and smallest of all because of marked concentration. One possible objection to Case's modification of the intravenous method is that, since no films are taken

until fourteen or fifteen hours after the injection, the information obtained about the concentrating activity of the gall bladder is less complete than if a series is made during the phase of concentration.

The chief points in making the diagnosis of cholecystic disease are: (1) Failure to obtain a shadow when the technique has been properly carried out: We agree with Carman,<sup>33</sup> in his statement based on a study of 1,100 cases, that a failure to obtain a shadow is unexcelled in diagnostic value. (2) Filling defects. Soft calculi which are otherwise invisible frequently are seen in the cholecystograms as "negative" shadows, or filling defects. They occupy space in the gall bladder which would otherwise be filled with the opaque substance. Many small stones often produce a mottled appearance which is very characteristic. (3) Irregularities of contour, denoting adhesions, diverticula, etc. (4) Variations from the normal in density of shadow, in the time of appearance and disappearance of the shadow. These last criteria are more difficult points to interpret than the former, and they constitute most of the failures in diagnosis. Other difficulties of interpretation have been encountered in certain cases of hepatic enlargement of unknown etiology.

If the new substance, phenoltetraiodophthalein, is used the time of examination can perhaps be shortened. This substance seems to pass through the liver more quickly than the others, with the result that usually at the end of four hours a moderately dense shadow of the gall bladder is seen.

Up to May 20th, 1926, we had examined at the Barnes Hospital 1,041 patients with tetraiodophenolphthalein and 103 with phenoltetraiodophthalein, a total of 1,144 patients with one or the other of the iodine compounds. In this series there were 128 operations at which the gall bladder was removed and an opportunity provided for a microscopic examination of it. On this basis the operation confirmed the Roentgen-ray diagnosis in 124 cases. Thus, the cholecystographic diagnosis was corroborated in 96.9 per cent. of the cases in which there was an opportunity to control it accurately. The examinations were divided as follows:

| <i>Tetraiodophenolphthalein.</i> |     |     |                            |
|----------------------------------|-----|-----|----------------------------|
| Intravenous                      | ... | ... | 750 cases (72.0 per cent.) |
| Oral                             | ... | ... | 289 cases (27.8 per cent.) |
| Rectal                           | ... | ... | 2 cases (0.2 per cent.)    |
| Total                            | ... | ... | 1,041                      |
| <i>Phenoltetraiodophthalein.</i> |     |     |                            |
| Intravenous                      | ... | ... | 97 cases (94.2 per cent.)  |
| Oral                             | ... | ... | 6 cases (5.8 per cent.)    |
| Total                            | ... | ... | 103                        |

Concerning toxic reactions, we have had no alarming symptoms in any of the last 500 cases. In seeking the data for the following tabulations it has been our custom to ask the patient to observe himself closely for the development of the slightest subjective symptoms. It is probable that often the alleged effects of the administration of the material have been imaginary, owing to the apprehensiveness of the patient. At most they have been transient. For convenience of classification the reactions have been divided into two kinds: In "1st degree" are included headache, dizziness, slight nausea, weakness, and "nervousness." In "2nd degree" are diarrhoea, vomiting, severe nausea, pain in back and abdomen, fever, "smothering," chills, and urticaria. The tabulated results are as follows:

| <i>Reactions in the last 300 Cases of Tetraiodophenolphthalein.</i> |     |     |   |
|---|-----|-----|---|
| <i>Intravenous method:</i>  |     |     |   |
| Total number of cases   | ... | ... | 205                                     |
| Cases showing reaction:   | ... | ... |   |
| 1st degree reaction   | ... | ... | 73 cases (35.6 per cent.)               |
| 2nd degree reaction   | ... | ... | 36 cases (17.5 per cent.)               |
| Total   | ... | ... | 109 cases (53 per cent. of intravenous) |
| <i>Oral method:</i>   |     |     |   |
| Total number of cases   | ... | ... | 93                                      |
| Cases showing reaction:   | ... | ... |   |
| 1st degree reaction   | ... | ... | 17 cases (18.2 per cent.)               |
| 2nd degree reaction   | ... | ... | 45 cases (48.0 per cent.)               |
| Total   | ... | ... | 62 cases (66 per cent. of oral)         |
| <i>Rectal method:</i>   |     |     |   |
| Two cases. No reaction.   |     |     |   |

| <i>Reactions in 103 Cases of Phenoltetraiodophthalein.</i> |     |     |  |
|--|-----|-----|--|
| <i>Intravenous method:</i>                                 |     |     |  |
| Total number of cases                                      | ... | ... | 97                                     |
| Cases showing reaction:                                    | ... | ... |  |
| 1st degree reaction  | ... | ... | 24 cases (24.7 per cent.)              |
| 2nd degree reaction  | ... | ... | 12 cases (12.4 per cent.)              |
| Total  | ... | ... | 36 cases (37 per cent. of intravenous) |
| <i>Oral method:</i>  |     |     |  |
| Total number of cases                                      | ... | ... | 6                                      |
| Cases showing reaction:                                    | ... | ... |  |
| 1st degree reaction  | ... | ... | 2 cases                                |
| 2nd degree reaction  | ... | ... | 1 case                                 |
| Total  | ... | ... | 3 cases (50 per cent. of oral)         |

Two facts stand out prominently from these tabulations: (1) that fewer toxic reactions occur after the intravenous than after the oral method of administration, this fact being especially noticeable as regards the more severe or second degree reactions; and (2) that the use of phenoltetraiodophthalein is accompanied by fewer reactions than tetraiodophenolphthalein.

Occasionally criticisms have been raised against the diagnostic value of cholecystography on the ground that sometimes a normal series of shadows is obtained when at subsequent operation pathological changes are found in the gall bladder. Richter,<sup>31</sup> for example, in a recent article, calls attention to the recurrence of attacks of gall-bladder disease, and states that probably in the intervals and in the early stages of disease the cholecystographic examination would show a normal gall bladder and hence would be misleading. It is possible that this fear may be correct, but, so far as I know, there are no data to support it. Our own experience is all opposed to this possibility. Richter apparently falls into the common error of regarding "thick tar-like bile" in the gall bladder as pathological. On the contrary, of course, such bile is a normal finding, and it is a clear indication of the fact that the concentrating function of the gall bladder is not impaired. It is our belief also that cholecystography, when properly performed, will give evidence of disease before it is recognizable by any method short of microscopic examination of the gall bladder. This has been our experience repeatedly.

Questions such as these bring up for consideration the more important question of what criteria shall be taken for determining abnormality. Is an organ that is functioning normally to be considered as essentially normal in spite of old evidence of disease? Or are we to conclude that even old pathological lesions—as, for example, adhesions—are to be taken as evidence of active disease demanding treatment? If its function is normal we do not consider a finger diseased simply because it may present an old scar as evidence of a previous infection. It is possible, therefore, that a functional test of the gall bladder, such as is made possible by cholecystography, will really prove to be a more accurate index of the actual condition of the organ than gross pathological anatomical findings at operation. But diagnoses of normality in the presence of a clinical history and clinical findings suggestive of cholecystitis should be made with caution, and only after experience with the method.

#### THE MECHANISM OF EMPTYING OF THE GALL BLADDER.

Cholecystography, in addition to its clinical application, has been useful in studying the physiological problem of the mechanism of emptying of the gall bladder. In 1917 Meltzer<sup>35</sup> published his now famous hypothesis of the contrary innervation of the sphincter of Oddi and of the gall bladder, by which was meant that a relaxation or opening of the sphincter was accompanied by a simultaneous contraction of the gall bladder. This hypothesis was rather generally accepted, and upon it was based the well known Lyon<sup>36</sup> procedure of the so-called non-surgical drainage of the gall bladder by the use of instillations of magnesium sulphate into the duodenum. But as a matter of fact there is little experimental evidence to support Meltzer's conception.

If any contraction of the musculature of the gall bladder occurs it must be exceedingly slight and of little significance. My associates and I, as well as others, have

repeatedly watched the visualized gall bladder with the fluoroscope with the hope of detecting contraction waves, but we have never seen any. It is significant also that, so far as I have been able to discover, only one surgeon has claimed to have seen the gall bladder contract. Matsuo,<sup>37</sup> a Japanese surgeon, states that once he saw it contract during the course of an abdominal operation performed under local anaesthesia. When one considers the millions of abdominal operations which have been performed both on the human subject and on experimental animals, it seems strange that contractions have not been frequently observed if they occur. Moreover, it is a striking fact that stimuli which are well known to have the power of inducing vigorous contractions in the urinary bladder and in the stomach and intestine fail utterly to elicit any visible response when applied to the gall bladder. Thus one can stimulate it with an electric current, as was first shown by Boyden and Whitaker and later corroborated by us, pinch it with a clamp, incise it with a knife, or touch it with a cauter, without the least demonstrable contraction. Periodic contraction waves, however, have been described by Bainbridge and Dale,<sup>38</sup> and later by others. These have been noted by observing and registering periodic changes in pressure within the organ. But these waves are usually synchronous with respiratory movements, and they seem to be caused by such movements rather than by any inherent contraction of the muscle of the gall bladder itself. My associates Copher and Kodama<sup>39</sup> have found, for example, that if care is taken to prevent the pressure of neighbouring organs upon the gall bladder the periodic contraction waves are no longer apparent. Moreover, if a rubber bag be substituted for the gall bladder, periodic contraction waves, like those described by Bainbridge and Dale, can be recorded. They can scarcely, therefore, be considered as due to contractions of the muscle of the gall bladder. Boyden has called attention to the comparatively small amount of muscle tissue present, but, on the contrary, to the large amount of elastic tissue in the wall. One would expect also that if a muscular contraction occurs in a manner analogous to that of the urinary bladder or of the stomach the gall bladder would sometimes be found practically empty. Yet I know of no observation that a normal gall bladder has ever been found in this condition. Cholecystography should again be of help in elucidating this point. But, although the gall bladder is seen by this means to reduce its size, there is no evidence that this diminution has been accomplished by a contraction of its muscle. Copher<sup>40</sup> has shown that if one daily injection of tetraiodophenolphthalein is given to a dog over a period of several days, the gall bladder is always visible during the time of the experiment, despite the fact that the animal is permitted to carry out its normal activities as regards food, exercise, etc. The results of this experiment furnish a strong indication that the gall bladder can never be empty under normal conditions. All of these observations, therefore, suggest that contraction of the muscle of the gall bladder must play an insignificant part in its emptying. How, then, does it empty itself of its contents?

Without the aid of muscular contractions other possible mechanisms of emptying are: (1) abdominal pressure, either with or without the assistance of respiratory movements; (2) a gradual washing out of the gall bladder by the ingress of fresh liver bile; (3) elastic recoil of the over-distended viscus when the pressure in the common duct is suddenly reduced by the opening of the duodenal end of the duct; and (4) absorption of its contents through the wall. The last possibility needs hardly to be considered seriously, since the evidence is incontrovertible that, except for the absorption of water, the contents of the gall bladder normally pass down the cystic duct and into the intestine. The thick dark bile of the gall bladder can even be recovered with the duodenal tube. There is also much other evidence which I feel unnecessary to mention here.

Recently it has been possible to show that the gall bladder can empty itself by calling into play only the two mechanisms of a gradual washing out by the inflow of fresh liver bile and of elastic recoil. Most of the experimental work involved has been performed by my associates Copher and Kodama, and our report of it has not yet been published.<sup>41</sup> The most decisive experiment bearing on this

point has been as follows: The gall bladder of a normal dog was removed and for it a small rubber bag was substituted, establishing a connexion with the cystic duct by means of a glass cannula. The artificial gall bladder was then encased in a collodion cylinder in order to obviate the effect of intra-abdominal pressure. After an intravenous injection of tetraiodophenolphthalein the artificial gall bladder became clearly visualized and gradually lost its visibility in a manner quite analogous to what we are accustomed to see in a series of normal cholecystograms. The chief differences from the normal series were that the shadow appeared more slowly and disappeared more slowly. These differences were probably due to an obvious inability on the part of the rubber gall bladder to concentrate its contents, the absence of the factor of intra-abdominal pressure, which probably plays a role of some importance in the normal emptying, and the fact that the distensibility and elastic recoil of the rubber bag were not identical with those of the normal gall bladder. Kodama<sup>42</sup> has devised an ingenious model to show how it may be possible for the gall bladder to empty itself without the aid of active contractions of its wall. His article will appear in a forthcoming number of the *American Journal of Physiology*.

These findings are opposed to the current conception that certain substances—as, for example, magnesium sulphate and pituitrin—empty the gall bladder by causing a contraction of its walls. How, then, do they act? To answer this question it is necessary to consider the duodenal end of the common duct. Since Oddi's description of the sphincter which bears his name it has generally been agreed that this structure is a factor of great importance in controlling the outflow of bile into the duodenum. Recent anatomical study, however, has shown that it is not always present. Again, as shown by the work of Copher and Kodama, it is unnecessary to assign to the sphincter the chief control of the outflow of bile. It will be recalled that the common duct passes obliquely through the duodenal wall for a considerable distance. According to Quain,<sup>43</sup> in human beings this distance amounts to 2 or 3 cm. Contractions of the duodenal wall would therefore tend to occlude the common duct independently of the sphincter at the end. Conversely, also, relaxations of it would permit bile to flow out unless the sphincter acted independently. Experimentally bile may be seen to spurt out of the ampulla with each peristaltic wave of the duodenum. The initial relaxation phase, followed by the contraction phase of each peristaltic wave, would have a "milking" effect on the duct. Each peristaltic wave of the duodenum, therefore, should result in some elastic recoil of the gall bladder itself, by which there would be a spurting out of a little of the gall-bladder bile. Likewise, these substances which induce most active duodenal peristalsis should be most powerful in their ability to empty the gall bladder. At any rate, the supposedly specific effect of pituitrin and magnesium sulphate in emptying the gall bladder seems to depend chiefly, if not entirely, on the production of duodenal peristalsis. Moreover, these substances are not nearly so powerful in this respect as certain fats—for example, egg-yolk and cream, as shown by Boyden. Sosman, Whitaker, and Edison<sup>44</sup> have found that a meal containing egg-yolk and cream can reduce the cholecystographic shadow of the gall bladder to about one-tenth of its former size within the brief time of one hour and forty-five minutes. Copher and Kodama have found that oleic acid is even more powerful in this respect. Burget<sup>45</sup> and Carlson<sup>46</sup> have also stressed the importance of the tonus of the duodenal muscle in the control of the outflow of bile, and they consider that undue importance has been attached to the supposed sphincter of Oddi.

My associates and I think, therefore, that the experimental evidence is all against Meltzer's hypothesis of the contrary innervation of the sphincter of Oddi and the gall bladder, by which it was supposed that the same stimulus which opens the sphincter induces an active contraction of the muscle of the gall bladder. On the contrary, we feel that the emptying of the gall bladder is largely a passive phenomenon in which occur: (1) the recoil of the elastic fibres in an effort to establish an equilibrium of pressure between the lumen of the gall bladder and that of the common duct when the intraductal pressure is suddenly lowered by the opening

of its duodenal end; (2) the washing out of the gall bladder by the inflow of fresh hepatic bile; and (3) increases in intra-abdominal pressure. Moreover, in the control of the outflow of bile from the common duct, the most important factors seem to be the tonus and the peristaltic movements of the duodenal muscle.

## SUMMARY.

1. The pathogenesis of cholecystitis is discussed and evidence is given to show that one neglected idea of its origin is by way of the lymphatics from a pre-existent hepatitis.
2. The frequent association of cholecystitis with other inflammatory lesions of the portal system is perhaps explained on this basis.
3. Cholecystography is a test of the only two functions of the gall bladder known at present. Partly because of this reason it will detect even early and comparatively mild cases of cholecystitis.
4. In our hands it has been the means of accurately diagnosing 96.9 per cent. of the cases controlled by operation in a series of 1,144 patients in which cholecystectomy was performed 128 times.
5. The severe toxic reactions have been practically eliminated.
6. Phenoltetraiodophthalein has many advantages over tetraiodophenolphthalein.
7. The mechanism of emptying of the gall bladder is discussed, and much doubt is cast upon Meltzer's hypothesis of a contrary or reciprocal innervation between the sphincter of Oddi and the gall bladder.
8. The muscle of the gall bladder seems to play at most a very minor role in its emptying.
9. The mechanism of emptying seems, on the contrary, to be largely passive, in which important factors are the elastic recoil of a distensible viscus, gradual washing out of the gall bladder by the ingress of fresh hepatic bile, and increases in intra-abdominal pressure.
10. A rubber bag substituted for the gall bladder in a living animal fills and empties in a manner very similar to the normal gall bladder.
11. The control of the outflow of bile from the common duct is dependent chiefly upon the tonus of the duodenal wall.
12. Those substances which are supposed to have a somewhat specific effect in emptying the gall bladder probably owe their action chiefly to their ability to induce peristalsis of the duodenum, with a resultant milking action of the common duct.

### THE DIAGNOSIS AND TREATMENT OF CHOLECYSTITIS AND THE PREVENTION OF GALL STONES.

GALL STONES are found in about 10 per cent. of the bodies of all people dying after the age of 20. Since in most, if not all, cases their formation is preceded by cholecystitis, and as cholecystitis is often not followed by cholelithiasis, the former must occur at some period in the lives of a considerable proportion of all adults. It is, I am convinced, the most common of all abdominal diseases. In spite of this it is comparatively rarely diagnosed, largely owing to the fact that until quite recently textbooks of medicine gave most inadequate descriptions of the symptoms and diagnosis of the common mild form of chronic cholecystitis, attention being almost confined to the comparatively rare and consequently much less important suppurative and gangrenous forms of the disease.

Every general practitioner must constantly have numerous cases of cholecystitis among the chronic dyspeptics under his care, but how often does he make the diagnosis? He realizes that in most cases the presence of gall stones calls for the help of a surgeon; he should recognize that chronic dyspepsia, which does not quickly yield to treatment, calls just as loudly for the help of a diagnostic team, consisting of a clinician, a radiologist, and a pathologist, since it is only by the use of certain

modern methods of investigation, which require special experience for their performance and for the interpretation of the results, that cholecystitis can be diagnosed with a considerable degree of certainty, and a scientific basis can be obtained for the rational treatment of each individual patient. The investigation should be sufficiently complete to decide whether any other conditions, such as a gastric or duodenal ulcer, chronic appendicitis, caecal and ascending colon stasis, and achlorhydria or hyperchlorhydria, are associated with it.

A carefully taken history should in most cases arouse suspicion when cholecystitis is present. Everybody should be familiar with Sir Berkeley Moynihan's classical description of the "inaugural symptoms of gall stones," which are now recognized as the symptoms of cholecystitis, having no direct connexion with the presence of stones. The abdomen should, if possible, be examined at a time when the patient is actually suffering from discomfort; the gall bladder itself is then always found to be tender. In this connexion I was surprised that Dr. Graham did not mention what I have myself found the chief use in the milder forms of cholecystitis, as distinct from gall stones, of the wonderful new method of visualizing the gall bladder which we owe to him—I refer to the palpation of the visualized gall bladder under the x-ray screen. Just as tenderness in the right iliac fossa should never be regarded as due to a tender appendix until the visualized appendix has been palpated under the x-ray screen, so tenderness in the right hypochondrium should now never be regarded as certainly due to a tender gall bladder, and not to a tender liver or duodenal bulb, until an examination has been made with the aid of cholecystography. I believe that there are many cases of slight, non-surgical cholecystitis in which this is the only radiological sign of disease.

Areas of referred tenderness, for many of the details of which we are indebted to the recent investigations of J. A. Ryle, are of great importance, and in a large proportion of cases reflex rigidity of the right hypochondrium is also present.

The radiological investigation should not only comprise Dr. Graham's method, but also a preliminary search for biliary and renal calculi, and an examination after an opaque meal of the stomach, duodenum, appendix, and colon, for such complications as ulcer, chronic appendicitis, and stasis of the ascending colon.

I am not convinced by Dr. Graham's arguments that the gall bladder does not actively contract when magnesium sulphate is introduced into the duodenum. The sudden abundant flow of bile which follows could hardly be explained in any other way; and how is it possible to explain the occurrence of biliary colic when a stone is impacted in the mouth of the cystic duct except by active spasmodic contractions of the gall bladder?

By Lyon's method it is possible to recognize inflammatory exudates from the mucous membrane of the gall bladder, such as leucocytes, disintegrated columnar epithelial cells, and occasionally red blood corpuscles, and to determine the nature of any biliary infection which may be present. It is interesting to note that in the late stages, when cholecystitis has become complicated by the presence of gall stones, the bile generally becomes sterile, any persisting infection being then confined to the wall of the gall bladder and perhaps the stones, while crystals of cholesterol, which are never found in the bile of uncomplicated cholecystitis, often appear. We have quite failed to confirm Rosenow's theory of the streptococcal origin from the teeth and tonsils of most cases of cholecystitis, as the infection is almost always due to pathological types of coliform bacilli, and streptococci have only been found in a single case. In one woman with cholecystitis and gall stones Dr. Knott isolated the *B. typhosus* from the bile obtained through a duodenal tube twenty-three years after she had had typhoid fever. When Graham's method fails to give a shadow of the gall bladder, it is clear that the Meltzer-Lyon method will also fail to procure a specimen of bile from the gall bladder. This explains the occurrence before the introduction of cholecystography of cases in which normal bile was found, but in which the gall bladder was grossly diseased and perhaps filled with stones, the bile having

come from the healthy hepatic ducts and not from the gall bladder. It is therefore best always to let the cholecystography precede the examination by Lyon's method.

Lastly, a fractional test meal should always be given, as either hyperchlorhydria, or, more frequently, hypochlorhydria or achlorhydria, is present in a large proportion of cases. The discovery of this is often of considerable importance; thus, a patient with achlorhydria may continue to suffer from symptoms due to this cause after his gall-bladder disease has been cured either by medical or surgical means if he is not given acid.

#### Treatment.

The medical treatment of cholecystitis, in the stages in which the bile is infected but the wall of the gall bladder is either not infected at all or only superficially or slightly infected, often leads to complete recovery. As there are no means of recognizing which cases will respond to medical treatment, it should always be given a trial in uncomplicated cases. Even in cases of gall stones with infective cholangitis, unless the symptoms are very urgent, a few days' preliminary medical treatment will often convert a very dangerous septic operation into a comparatively safe one.
